CANCER OF THE RECTUM*

An Analysis of Cases Occurring in Connecticut during 1935-1945†

EDWARD J. OTTENHEIMER, M.D.‡

WILMINGTON, CONNECTICUT

IN 1935 a plan was inaugurated in Connecticut whereby duplicate copies of hospital records of patients with cancer were made available to the Division of Cancer Research of the Connecticut Department of Health. This was a joint undertaking sponsored by the Tumor Committee and the Association of Tumor Clinics of the Connecticut State Medical Society, the general hospitals of the state, and the State Department of Health. As a result of fortuitous co-operation, complete data on over 35,000 cases of cancer have been collected and are now available for analysis.

This study is concerned with all cases in which a diagnosis of cancer of the rectum was made in the eleven-year period from 1935 to 1945 inclusive. The patients were admitted to twenty-seven general hospitals, representing approximately 95 per cent of all general-hospital beds in the state. Ward as well as private patients were included, so that no economic level was ignored. The patients were treated by many surgeons in both large and small hospitals. Complete follow-up data were obtained in over 97 per cent of cases. A significant and perhaps unique attempt is therefore made to present a true picture of cancer of the rectum on a state-wide basis.

Incidence

Cancer of the rectum represented between 4 and 5 per cent of all cases of the disease (Table 1). Although the admission rate of patients with cancer per 100,000 population rose from 131.1 in 1935 to 256.0 in 1945, the percentage of patients with cancer of the rectum rose proportionately to maintain an incidence of 4 or 5 per cent.

In the eleven-year period, 1610 patients were admitted to hospitals with the diagnosis of cancer of the rectum. Of these cases, 1188 were proved microscopically, and in 422 the diagnosis was made

clinically. Only six hospitals had more than 100 cases of cancer of the rectum in the period, and the total number of cases was 983, or 61 per cent of the grand total, twenty-one hospitals had less than 100 cases, representing 39 per cent of the total. Of the microscopically proved cases, 777, or 65.5 per cent, were found in the hospitals with more than 100

TABLE 1 Mortality and Admission Rates for All Cancer and Incidence of Cancer of Rectum

YEAR	AGE ADJUSTED MORTALITY FOR ALL CANCER per 100,000	CRUDE MORTALITY FOR ALL CANCER per 100,000	ADMISSION RATE FOR ALL CANCER per 100,000	ADMISSION RATE FOR CANCER OF RECTUM per 100,000	INCIDENCE OF CANCER OF RECTUM %
1935	111.6	133.3	131.1	6.8	5
1936	107.3	122.5	136.5	5.3	4.0
1937	103.3	122.5	150.0	6.1	4.1
1938	114.9	143.9	153.4	7.1	4.7
1939	112.3	143.0	179.0	8.0	4.5
1940	118.3	151.1	171.5	8.2	4.8
1941	117.6	154.1	195.0	9.4	4.8
1942	118.0	157.6	203.1	8.2	4.0
1943	118.4	160.9	210.0	10.0	4.8
1944	118.5	169.5	207.0	10.4	5.0
1945	114.2	160.2	256.0	10.4	4.1

cases, and 411 cases, or 34.5 per cent, were discovered in the others.

The incidence of proved cases rose from a low of 58.7 per cent in 1935 to a high of 83.3 per cent in 1942. In this period 73.9 per cent of cases were proved microscopically. In the hospitals with more than 100 cases, 79 per cent of cases were proved microscopically, and in the others only 65.6 per cent were proved (Table 2). Although, in the absence of microscopical evidence of cancer, no scientifically valid conclusions can be drawn, in a high percentage of the unproved cases a diagnosis of cancer of the rectum seemed justifiable. Furthermore, the longevity curve of 220 unproved cases in the first six years coincided almost exactly with that plotted by Daland, Welch and Nathanson¹ for 100 untreated cases of cancer of the rectum, 35 per cent of which were proved microscopically, and with a similar curve plotted for 67 untreated proved cases in this series. For these reasons, wherever it appears, to be

*Presented at the annual meeting of the New England Surgical Society, Worcester, October 4, 1946.

†The tables and analyses are from the registry of the Division of Cancer and Other Chronic Diseases, Connecticut State Department of Health, Hartford, Connecticut.

‡Chief surgeon, Windham Community Hospital.

of importance, data on unproved as well as proved cases are presented to obtain a broad comprehension of the present status of cancer of the rectum in the state

Age

The age distribution in the total proved and unproved cases is presented in Table 3. Slightly over

TABLE 2 *Distribution of Cases according to Microscopical Proof*

YEAR	MICROSCOPICALLY PROVED CASES		CASES NOT PROVED		TOTAL CASES
	NO	PERCENTAGE	NO	PERCENTAGE

Hemorrhoids of over six months' duration	132	8.4
Vomiting	128	8.2
Mucus	106	6.8
Polyps	91	5.8
Rumbling of gas	76	4.8
Urinary symptoms	69	4.4
Hemorrhoids of less than six months' duration	46	2.9

proportion of patients in the age groups above seventy than is usually found in the literature.

Heredity

On the basis of proved cases alone, 4.9 per cent of patients had relatives with cancer at the same site, and in 2.7 per cent of these cases the relative was a parent (Table 4). It should be pointed out that information on heredity was not obtained in 48.2 per cent of cases. If this number of patients is deducted from the total, and rates are based only on cases known to have been questioned, 19.8 per cent had relatives with cancer, and 9 per cent had relatives with cancer of the rectum. The figures are too small to be conclusive, however.

Signs and Symptoms

The usual presenting symptoms were rectal bleeding, weight loss and some change in bowel habit.

TABLE 6 *Complicating Diseases on Admission*

DISEASE	NO OF CASES	PERCENTAGE
Hypertension or arteriosclerosis	156	10.0
Heart disease	75	4.7
Diabetes	36	2.3
Gastric ulcer	16	1.0
Kidney disease	13	0.8
Pernicious anemia	6	0.4

(Table 5). Local pain and tenesmus were also frequent. The high incidence of weight loss, abdominal pain and vomiting attests to the advanced stage of many cases. Over 11 per cent of patients gave hemorrhoids as the first symptom, and many of these patients had been treated surgically before the cancer was discovered.

In addition, about 20 per cent of patients were found to have some complicating organic disease, notably of cardiovascular origin (Table 6). Diabetes was present in 2.3 per cent, and gastric ulcer in 1.0 per cent of cases. These incidental findings are

probably not unusual in the light of the age groups involved

Duration of Symptoms

The average delay between the onset of first symptoms and receipt of treatment is presented in Table 7. The median delay in 1935 was 11.2 months.

TABLE 7 Delay between Onset of First Symptoms and Treatment

YEAR	DELAY OF ONE MONTH %	DELAY OF FOUR MONTHS %	DELAY OF SIX MONTHS %	AVERAGE DELAY MO
1935	10.0	31.0	43.6	11.2
1936	7.9	27.8	43.4	8.9
1937	16.4	31.0	51.0	6.9
1938	18.3	45.0	59.1	5.8
1939	17.2	35.8	47.8	7.8
1940	17.0	39.0	53.9	6.6
1941	18.5	39.7	56.0	6.1
1942	21.4	40.0	55.0	6.6
1943	17.6	41.2	54.6	6.5
1944	22.3	46.1	54.8	6.3
1945	20.0	41.0	55.0	6.6

In the subsequent two years, the average dropped to 6.9 months, but no appreciable improvement has occurred in the past eight years. The median delay seems to be fixed between six and seven months. The percentage of patients receiving definitive treatment within one month of the first symptom, however, has doubled in eleven years—from 10 to 20 per cent. The percentage of those receiving treatment within four months has risen from 31 to 41 per cent, and within six months from 44 to 55 per cent.

Diagnosis

Delay in the recognition of cancer of the rectum should be minimal in view of the striking early symptoms, which focus the attention of both the

TABLE 8 Results of X-ray Diagnosis

NO OF CASES EXAMINED	POSITIVE FINDINGS		NEGATIVE FINDINGS		QUESTIONABLE FINDINGS	
	NO	PER CENTAGE	NO	PER CENTAGE	NO	PER CENTAGE
438	348	79.6	43	9.7	47	10.7

patient and the physician on the lower bowel. Furthermore, in most cases, by the time the first symptoms appear, the disease has already been present sufficiently long to be discovered easily by a careful digital examination. Proctoscopic examination, as well as biopsy, is of value in revealing the few cases that may be difficult to detect with the finger. The value of x-ray diagnosis is indicated somewhat in Table 8.

Only 37 per cent of patients with proved cases had an x-ray examination. In slightly over 20 per cent

the diagnosis was either negative or doubtful. In some Connecticut clinics, radiologists, cognizant of this wide margin of error, now do digital examinations on every patient referred for a barium enema.

Histologic Grade of Cancers

Connecticut clinics use only three histologic grades. Tissues that might be interpreted as Grade IV according to Broders's¹ classification are included in Grade III. Of the microscopically proved cases 123, or 10.3 per cent, were classified as Grade I, and 582, or 49.0 per cent, as Grade II, thus, nearly 60 per cent of cases were either Grade I or Grade II. Only 110 cases, or 9.3 per cent, were Grade III. In 31.4 per cent the grade was not stated, which

TABLE 9 Resectability according to Year of Admission

TOTALS ALL GRADES	621	1188	52.3	1610	38.6

may or may not reflect a trend away from grading in the state.

Stage of Disease

The extent of the growth in all cases was described as either localized, with involvement of regional lymph nodes or with remote metastases, corresponding in general to Dukes's² classification of A, B and C. In the entire period 707 cases (59.5 per cent) were localized, 316 (26.6 per cent) showed regional involvement and 116 (13.9 per cent) had remote metastases on admission. The number of localized cases was 309 (60.0 per cent) between 1935 and 1940 and 398 (59.2 per cent) between 1941 and 1945. The number of patients admitted between 1935 and 1940 with regional involvement—117, or 22.7 per cent—increased over 6 per cent in the last five-year period, to 199, or 29.5 per cent, and this coincided with a drop from 89 (17.3 per cent) to 76 cases (11.3 per cent) with remote metastases in the corresponding periods.

Resectability

Resectability is determined essentially by the skill and experience of the surgeon, as well as by his attitude toward the choice of radical surgery as a palliative measure in the presence of extensive disease.

In the eleven-year period, the average number of patients admitted annually to the twenty-seven

hospitals was 108. It is apparent that under the present system no one surgeon in the entire state has had an opportunity to do a large series of cases. This must be considered in the evaluation of the

TABLE 10 *Resectability according to Number of Admissions.*

SOURCE OF DATA	TOTAL PROVED AND UNPROVED CASES	TOTAL PROVED CASES	RESECTIONS	RESECTABILITY OF PROVED CASES %	TOTAL RESECTABILITY %

figures, however, are based on microscopically proved cases only. If all cases are considered, proved and unproved, the rate ranged from 32.2 per cent to 48.7 per cent, and was 38.6 per cent for the

Treatment

Radical resections were performed in 621, or 52.3 per cent, of microscopically proved cases and in 38.5 per cent of all cases. The procedures in the microscopically proved cases are presented in Table 11. Local excision was performed in 49 cases, usually those with polyps that had undergone malignant change. Only 2.7 per cent were treated by radiation alone, although a number of cases in the miscel-

TABLE 12 *Distribution of Resections*

YEAR	ONE STAGE PROCEDURES	TWO STAGE PROCEDURES	TOTALS

laneous group were treated by radiation combined with some operative procedure.

Of the 275 patients who had colostomies, 41 also had some form of radiation. The operative mortality for colostomies was 28 per cent. A careful study of the records of these cases was made to determine why radical treatment had not been attempted. Some of the patients were candidates for a two-stage resection, but did not survive the colostomy. Other cases were obviously inoperable, and colostomy was attempted as a palliative measure. Approximately 25 per cent of patients seemed to be in good condition on admission, and radical resections might have been attempted in bolder and more skillful hands.

Of the 105 patients for whom no treatment was recommended, 45 per cent were over seventy years

entire period. None of the patients with unproved cases had resections, but a different significance is attached to the rates when they are based on total cases rather than on microscopically proved cases alone.

The resectability rate in hospitals with more than 100 cases was 7 per cent higher for proved cases, and 12 per cent higher for total cases, than that in hospitals with less than 100 cases (Table 10).

of age, about 50 per cent were considered to be in poor general condition, and over 21 per cent had remote metastases on admission. The average duration of life from the first symptom to death for this group was 21.3 months.

The unproved cases were treated as follows: colostomy, 214 cases; no treatment, 187 cases; radiation, 15 cases; and miscellaneous, 6 cases. No unproved case was submitted to radical resection.

Of the 621 resections, 74.6 per cent were one-stage abdominoperineal operations, and 25.4 per cent were performed in two stages, either by the Lahev²

in 384 cases, with a mortality of 18.4 per cent. Similarly, in the period of 1935-1940 one-stage resections were done in 131 cases, with a mortality of

TABLE 14 Operative Mortality following Radical Resection

YEAR	ONE-STAGE RESECTIONS	OPERATIVE DEATHS	TWO-STAGE RESECTIONS	OPERATIVE DEATHS	ALL RESECTIONS	OPERATIVE DEATHS

method or by colostomy followed by perineal resection (Table 12).

There was a striking increase in the frequency of one-stage resections during the eleven-year period. Between 1935 and 1940 one-stage operations represented 55.3 per cent of total resections, and 44.7 per cent were done in two stages. In the past three years,

25.2 per cent. In the last five years, one-stage resections were performed in 332 cases, with a mortality of 16.5 per cent. In 1945 the mortality for one-stage resections had dropped to 14.7 per cent.

cardiovascular failure, including cerebral hemorrhage, myocardial failure, mesenteric thrombosis and ruptured aneurysm. Pulmonary embolism accounted for 8.4 per cent of deaths, and pneu-

Localized growths and a low histologic grading appear to be favorable factors.

Results

In reviewing the literature on cancer of the rectum in the past ten years, one is impressed with the lack of uniformity in reporting end results. This makes for ambiguity of interpretation and difficulty of comparison. In this series the method of computing five-year cures suggested by Martin⁴ was employed. Strict and logical criteria are established for determination of cure, and accurate follow-up study in over 90 per cent of cases is necessary. On this basis, five-year cures were obtained in 11.5 per cent of the 515 proved cases with known results observed during 1935-1940, and in 16.1 per cent of the resected cases (Table 17).

This estimation of cures, however, does not take into account the relatively large number of unproved cases. With the view of advocating the adoption of a standard method of reporting end results, the estimate was revised (Table 18). The variety of results that may be claimed, depending on the basis used for calculation, is apparent.

Beginning with a five-year-cure rate of 7.9 per cent based on all cases and a five-year survival rate of 12.8 per cent, there is a progressive rise to an optimistic figure of 35 per cent as different denominators are used. Statistics thus computed show the possibilities of accomplishment in selected cases, but tend to obscure the total picture.

Comparative longevity curves in resected cases, cases in which colostomies were performed, cases in which no treatment was given and unproved cases are presented in Figure 1.

* * *

Although a detailed and critical analysis of the findings is not possible in this presentation, sufficient information has been submitted to indicate the value of collecting cancer statistics on a state-wide basis.

A continued effort must be made to reduce the time lag between the first symptom and definitive

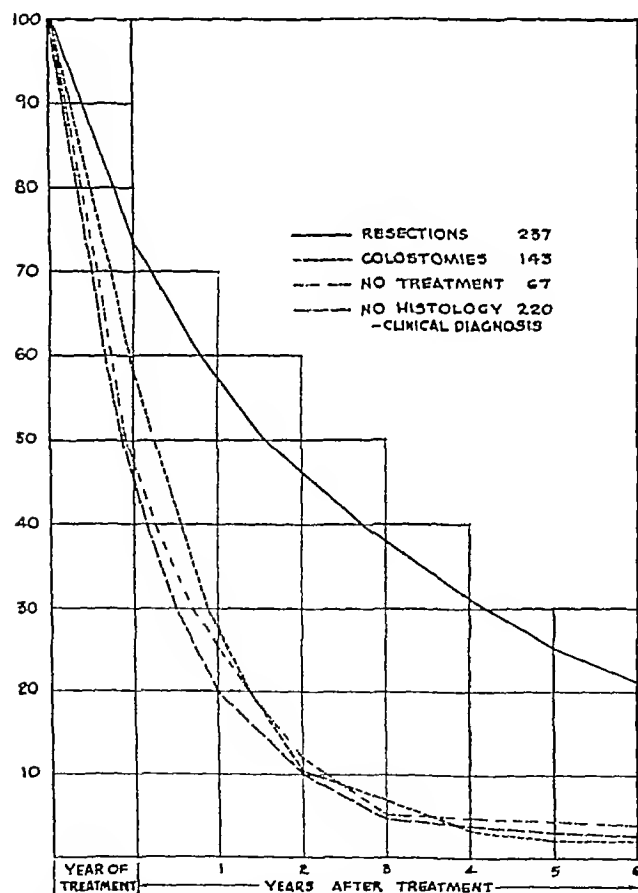

FIGURE 1 *Percentages of Survivals after Hospitalization for Cancer of the Rectum (based on the 1935-1940 records of twenty-seven general hospitals)*

monia and atelectasis for 7.9 per cent. Urinary complications caused 6.2 per cent of deaths.

Factors Influencing Cure

Data on factors that have been considered to influence curability are based on cases admitted

treatment. The signs and symptoms of cancer of the rectum are sufficiently striking to warrant early recognition by both the patient and the physician.

Biopsy should be performed in all cases if an accurate appraisal is to be made.

Operability and mortality rates are improving, owing perhaps to the use of antibiotics in the prevention and treatment of sepsis, a better understanding of the management of shock and phlebitis and the more widespread employment of trained physician-anesthetists. Further improvement might be possible if some plan could be adopted of concentrating the care of these cases in a few centers.

For the six-year period 1935-1940, five-year cures were obtained in only 7.9 per cent of all cases. In the microscopically proved cases 11.5 per cent of patients were cured at the end of five years. More favorable results can be shown in selected cases, as reported in the literature. This suggests that a uniform method of reporting end results is highly desirable in the interest of a precise evaluation of the status of cancer of any organ.

DISCUSSION

DR. ASHLEY W. OUGHTERSON (New York City): Ten years ago the Connecticut Tumor Society inaugurated this program, and this paper that we have had the privilege of hearing today is the first summary of 1610 cases of cancer of the rectum out of a total of more than 35,000 cancer cases.

Connecticut doctors should be congratulated since this represents some of the best of medicine as a social science, and there has been a great trend in recent years toward considering medicine a social science.

The general practitioner, the specialist, the State Department of Health and the hospitals have joined in a co-operative effort to discover what happens in one of man's most insidious and dangerous diseases.

The paper just presented is important because, to my knowledge, it represents the first time in America that a cross section of the population has been studied as treated and diagnosed by a cross section of the physicians. Such a study, and the remainder of these facts in Connecticut as they are brought out, should provide us with the sinews for the war against cancer to point the way to what is needed and to indicate the effectiveness of cancer control.

These results are obviously not so favorable as they could have been, but they are not so poor as they might have been. Much has been heard of the results to the large hospitals and clinics which have performed a great service in showing what can be done, but by this time we know that their results are good and we need to hear more of the other side of the story.

Medicine as a social science cannot be judged solely by the results to the large hospitals and clinics. One must go to the average hospital inhabited by the average patient, who is treated by the average physician, to evaluate the position of medicine as a social science.

This material is extraordinarily valuable at the present moment because of the attack on cancer in which many of us are engaged in inaugurating and guiding. The large sums of money that are becoming available raise a pertinent question—how this money should be spent. It has been stated that 30 to 50 per cent of patients with cancer can be saved by the proper or adequate use of the methods that are available. I doubt whether that figure is accurate because to my knowledge the facts have not been obtained from a cross section of the population.

Here, for the first time, is a co-operative effort within a state to furnish that information so that by proper analysis it can be stated with reasonable accuracy after this study is completed what can be accomplished by education in the use of the methods that are available. Then it can be determined how much of the national resources of money, men and materials should be spent on the use of the weapons at hand while research for the future is being conducted.

No one knows when the cause of cancer or a new means of cure will be discovered. Many authorities actually doubt whether there will be a universal cure. It is therefore imperative at present, when promises of what will be done to cure cancer are being made, to obtain concrete results.

INFECTIOUS HEPATITIS WITH SUBACUTE ATROPHY OF THE LIVER*

An Epidemic in Women after the Menopause

M. JERSILD, M.D.†

COPENHAGEN, DENMARK

AN unusual and serious epidemic of infectious hepatitis has been present in Denmark since 1944. It differs from epidemics previously described in that the course has been extremely malignant and the disease, which is usually fatal, occurs almost exclusively in women after the menopause.

In 1945 attention was called to this form of hepatitis in Denmark,¹ and several other observers have had similar experiences.²⁻⁴ Since in most patients the disease progresses in a characteristic and uniform manner, the symptoms by which it has generally been manifested in our department are described below.

As a rule the patient is an elderly or middle-aged woman. For a month or two she has suffered from lassitude, epigastric oppression, loss of appetite turning to an aversion to food and nausea. Occasionally, vomiting occurs. The patient is hospitalized for gradually increasing jaundice, which begins after the initial stage described above. At times the first symptom is a brief febrile period or perhaps diarrhea. During the subsequent course, however, the temperature is seldom high, the icterus varies in intensity but is often only moderate. It may last until exitus, but this is not the rule. The jaundice often has a tendency to recede while the patient is confined to bed, although this does not justify a more favorable prognosis. Since icterus may vary greatly within a relatively short time and there often are colicky pains in the right upper quadrant, it is not surprising that the differential diagnosis from cholelithiasis is difficult.

In the icteric stage the patient's appetite usually decreases. She complains of a bad taste in the mouth. The lassitude grows, and she may spend the whole day drowsing. Five or six months after the onset the patient is usually troubled by increasing ascites and edema. She may lie for months in this condition. With parched mucosa, ecchymosis, decubitus ulcers, massive ascites and edema, the patient is a wretched sight before passing at last into the phase of hepatic coma — an event that usually happens ten or twelve months after the appearance of the first vague symptoms.

The post-mortem findings are just as characteristic as those of the clinical picture. Usually, the liver is extremely atrophic, weighing only 600 to 800 gm. Even macroscopically the lesion seems distinguishable from the ordinary portal cirrhosis. The surface

is lighter in color than normal. In some areas there are small islands of preserved liver tissue, differing from the surrounding areas by their yellowish color and projecting somewhat from the general surface, which shows many retractions due to areas of atrophy where the liver cells are replaced by connective tissue. The cut surface shows similar features. Here, too, the predominant feature is the homogeneous connective-tissue stroma, with scanty areas of preserved liver tissue.

On microscopical examination the central part of the acinus is seen to be the site of degenerative changes, with incipient inflammatory infiltration. The central vein and capillaries are dilated, and the liver cells atrophic and necrotic. There is proliferation of the Kupffer cells and infiltration with leukocytes, lymphocytes and phagocytic cells. In the periphery of the acinus the liver cells are preserved fairly well, being arranged in columns or trabeculae. This is the picture encountered at a relatively early stage. When the process is more advanced, the greater part of the original liver parenchyma has disappeared, leaving merely scattered small islands of liver cells; the rest of the organ is made up of connective tissue rich in cells, with isolated groups of vessels.

The changes correspond exactly to the picture of subacute yellow atrophy of the liver described by Bergstrand⁵ in 1930, or to that in protracted cases of liver atrophy described by Lucké⁶ in 1944. Microscopically, the lesion differs distinctly from portal cirrhosis, in which the changes seem to have begun in the periphery of the lobule.

Even at an early stage liver-function tests indicate a grave parenchymatous lesion. The Takata reaction, which must be emphasized as a reliable test, is strongly positive in nearly all cases of chronic hepatitis. The icteric index is moderately high as a rule, fluctuates to some extent during the course of the disease and in the terminal stage may show normal values. The urobilinogen in the urine is generally increased. The thymol reaction is usually markedly positive, and the sedimentation rate increased, as is the relative globulin content of the serum.

The following is an account of the epidemic of chronic hepatitis observed since 1944 at Bispebjerg Hospital, Department B, chiefly among elderly and middle-aged women. For comparison I have collected all cases of infectious hepatitis recorded in the Department from 1928 to 1945, a total of 550 cases. Of these, 396 followed an acute course, — that is, the duration was under three months, — and

*From Bispebjerg Hospital (chief, Dr. E. Meulengracht). This study was supported by a grant from the P. Carl Petersen Foundation.

†Senior assistant in medicine, Bispebjerg Hospital.

154 were chronic—of more than three months' duration

Figure 1 shows that the number of chronic cases increased rapidly in 1944 and 1945, the total in these

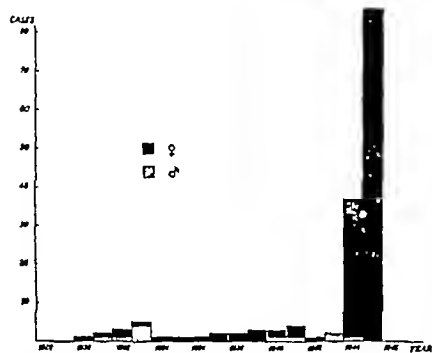

FIGURE 1 Infectious Hepatitis of More Than Three Months' Duration at Bispebjerg Hospital (Department B) during 1928-1945

two years being 123, whereas in the foregoing sixteen years there had been only 31 cases. It also appears that during the epidemic the chronic cases oc-

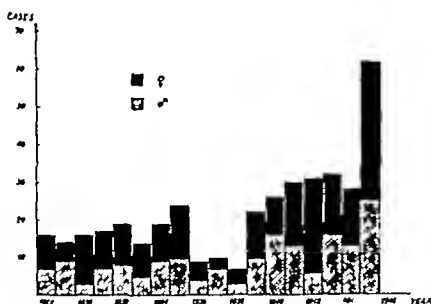

FIGURE 2 Infectious Hepatitis of Less Than Three Months' Duration at Bispebjerg Hospital (Department B) during 1928-1945

curred almost exclusively among women (1 male and 122 female patients)

Figure 2 presents the distribution of the 396 acute cases. The incidence was about equally distributed between the sexes, despite the fact that the women's department is larger than the men's.

Figure 3 comprises all cases of infectious hepatitis reported to the authorities from all over the coun-

try. It will be observed that there were two epidemics, the maximum number of cases occurring in one in 1933 and in the other in 1943, in the latter year there were 18,000 cases of infectious hepatitis (six times more than the normal) throughout the country, whose total population is 4,000,000.

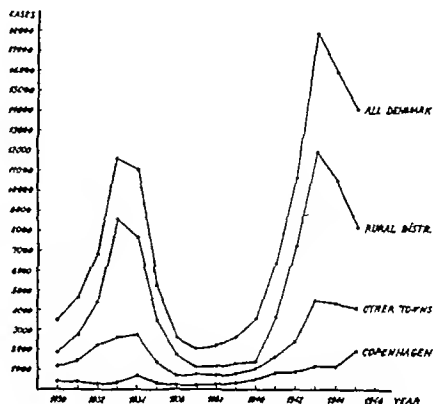

FIGURE 3 Infectious Hepatitis in All Denmark and Various Districts during 1930-1945

Figure 4 presents the fatal cases of infectious hepatitis, including acute and chronic atrophy of the liver. During the 1944-1945 epidemic 75 patients died, only 1 of them being a man, thus, nearly 99 per cent of the fatal cases occurred in women. Of all hospitalized patients with infectious hepatitis in these two years 35 per cent died, and in all cases with a duration of over three months the mortality

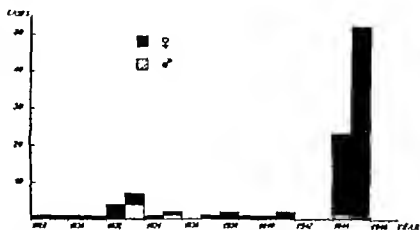

FIGURE 4 Fatal Cases of Infectious Hepatitis according to Sex, at Bispebjerg Hospital (Department B)

was 67 per cent. It is probable that this extremely high mortality will increase when the period of observation is lengthened.

Chronic hepatitis occurs chiefly in patients above fifty years of age (Table 1), 71 per cent of patients were over fifty, and 90 per cent over forty years, whereas the acute form usually affected people chiefly between the ages of fifteen and thirty. Eighty-

†Less than three months' duration

five per cent of the patients who died in 1944-1945 were over fifty years of age.

A characteristic feature of chronic hepatitis is the long preicteric phase in which the patients complain of tiredness, loss of appetite and weight. Table 2 shows that during the 1944-1945 epidemic the preicteric phase lasted more than a month in 64 per cent of the chronic cases, and in 32 per cent the duration was over two months. In 100 successive cases of acute hepatitis the preicteric phase lasted less than fourteen days in 92 per cent.

Ascites and edema are frequent complications in chronic hepatitis. These symptoms generally occur simultaneously. Of 123 patients 66 per cent had edema and ascites, in most cases about six months after the first manifestation of the symptoms, 6 of the patients never had jaundice. The duration of the chronic hepatitis, determined from the appear-

ance of the initial symptoms, in 75 fatal cases is presented in Table 3. The average duration was nine months.

The fulminant occurrence of malignant, protracted hepatitis in women after the menopause seems to be unique and has not previously been described in epidemics in or outside Denmark.

During an epidemic in Sweden in 1928 Bergstrand⁵ found that 72 per cent of the malignant cases of hepatitis occurred in women. There, however, the affection was apparently acute atrophy of the liver,

terminating fatally in the course of from four to six weeks. Of Bergstrand's patients 37 per cent were women over forty-five years of age.

Lucké⁶ describes 125 fatal cases during an epidemic of hepatitis among soldiers in 1942. Here again, acute atrophy of the liver led to death in four to six weeks. In both Bergstrand's and Lucké's material the preicteric initial phase did not last more than two weeks as a rule, as in the acute cases described above.

The natural assumption is that this is a disease previously unknown in Denmark and differing markedly from the ordinary form of infectious hepatitis. The chronic hepatitis in the 1944-1945 epidemic occurred chiefly among elderly women, whereas acute hepatitis attacked younger people with no particular regard to sex.

The chronic form often has a preicteric phase of several months' duration, with gradually increasing tiredness and nausea, whereas acute hepatitis gener-

ally has a preicteric phase of no more than a week, so that at the beginning of the jaundice one can often predict the course of the disease.

In chronic hepatitis the icterus often varies considerably in degree, sometimes, it subsides completely, even if the disease progresses. This is rarely true of the acute form.

Of the patients with chronic hepatitis 4 had previously had infectious hepatitis and had been well in the meantime. This suggests that the first attack left no immunity to the next one. Acute hepatitis rarely occurs more than once in the same patient if relapses are disregarded.

It seems possible for chronic hepatitis to be transmitted by contact, and for the person so infected the course is equally grave. In 4 cases of chronic hepatitis the lesion possibly arose through contact with other patients. These 4 patients were elderly women who for some time had nursed their respective female relatives who had been suffering from chronic hepatitis. The disease had an incubation period of up to two months in the 4 cases and followed a fatal course in the contacts as well as in the original patients.

There are certain points of resemblance between serum hepatitis and this chronic form. According to Findlay et al.,⁷ Havens⁸ and Neefe, Stokes and

Gellis,⁹ serum hepatitis has a long incubation period and sometimes a graver course than infectious hepatitis. It has never been demonstrated that serum hepatitis can infect by contact, nor in fact has such transmission been proved in chronic hepatitis. Since the infectious substance of serum hepatitis can be transmitted on the point of a knife that has been wiped after blood sampling from the ear, there does not seem to be anything improbable in transmission via an insect bite. Among the nurses in the department there has been no case of chronic hepatitis, although no special measures were taken to avoid infection.

I should not neglect to raise the question of whether these elderly women had suffered under dietary insufficiency, especially a protein deficiency. Since they were by no means particularly poor or underfed, this possibility may be ignored, especially because none of them presented signs of dietary insufficiency, indeed, no such symptoms were observed in Denmark during the war.

A feature common to almost all women with chronic hepatitis is that they had passed the menopause. In several of the younger patients with chronic hepatitis the menses failed while the affection lasted, sometimes for more than a year. On this basis it is tempting to assume that in some way the female sex hormone has a bearing on the course of the infection. The fact seems established that the estrogens are neutralized in the liver,¹⁰⁻¹² and certain hormonally conditioned changes have been observed in patients with liver lesions, such as gynecomastia and atrophy of the testes in males with cirrhosis of the liver.¹³

So far as the excretion of estrogens in this form of hepatic lesion is concerned, nothing has been done beyond certain initial investigations. Nevertheless, it is a problem that may become of practical importance, if it should turn out that in women the estrogens exert some form of liver-protecting influence against the infection.

SUMMARY

An account of an epidemic of chronic hepatitis in Copenhagen in 1944-1945 is presented. In a single department of a hospital 123 patients were treated for the disease, which is characterized by a protracted course (over three months) and by the occurrence of ascites and edema. Over 99 per cent of cases occurred in women. The mortality was high — 61 per cent. The disease chiefly affected women after the menopause, 79 per cent of patients during the epidemic being over fifty years of age, and is often characterized by a long preicteric phase — more than four weeks in 64 per cent — in contrast to acute infectious hepatitis, in which the preicteric phase in 92 per cent of patients was less than two weeks. The average duration of the disease in the fatal cases was nine months.

The possibility of a special malignant virus is emphasized, and the question is raised whether estrogens exert some form of liver-protecting influence against this particular infection.

BOSTON MEDICAL LIBRARY

Report of the President*

IT IS an annual custom for the President to inform the fellows of the condition of the Library. It is my pleasant duty to present my first annual report

The status of medical libraries in Boston has been a subject of discussion for some years. In 1941 a survey of this situation was made by Mr Thomas P Fleming, medical librarian of Columbia University, and his comprehensive report was studied by a committee consisting of Mr Fleming and Drs John F Fulton and Robert N Nye. This committee brought out the following points

In general, medical institutions in Boston have excellent resources of medical literature within relatively easy access

The physical facilities of the working libraries in the medical schools are in need of considerable readjustment

The administration of all working libraries has not attained general standards of medical libraries in other parts of the country

The Boston Medical Library is centrally located and has sufficient storage space for many years to come, particularly in view of the facilities offered by the New England Deposit Library

The Boston Medical Library, because of lack of funds, is understaffed and does not furnish the type of service, regarding either quantity or quality, that is to be expected

The future of the Boston Medical Library, particularly in view of present-day attempts to eliminate decentralization and duplication, hinges about its development as a *reference library*, for the benefit not only of Boston and its immediate vicinity but also of the rest of Massachusetts and the other New England states

The committee recommended that steps be taken to actuate these observations

The trustees have endeavored to find ways and means of accomplishing at least some of these suggestions. The results have been discouraging. Dr Cheever, in his last annual report, described in detail the various attempts to get more income. A drive for more fellows has brought in perhaps \$2500 more, the professional members at \$50 each have increased somewhat and the Suffolk District Medical Society and several special societies have been most generous. In spite of this, our income has averaged only about \$30,000 a year, and without expanding at all we run behind about \$1000 a year. That the Library has been able to offer any reasonable service has been due to the untiring

efforts of our librarian, Dr Viets, and of our director, Mr Ballard, and his small but devoted staff.

A library of over 200,000 volumes and almost as many pamphlets, to say nothing of its almost priceless collection of incunabula, Hebraica, early medical-history and biographic collections, which are of national importance, certainly deserves better and more widespread support

The Massachusetts Medical Society and the Boston Medical Library have grown up hand in hand. The founders of the Library were all members of the Society. Although the Massachusetts Medical Society gave its books to the Boston Public Library in 1872, it was apparently satisfied to turn to the Boston Medical Library as a place for its meetings and its general headquarters, and in February, 1879, it was voted "That the treasurer of the Society be authorized to conclude arrangements with the Boston Medical Library Association by which councilors of the Massachusetts Medical Society, together with its standing committees, . . . may hold their meetings at the rooms of the Library Association during a term of ten years." The Library has continued to be the headquarters of the Society ever since. In June, 1885, a recommendation of the Committee on Library, through Dr Z B Adams, stated that the library of the Massachusetts Medical Society consisted mainly of reports of various medical societies, and it was voted "That that property and all similar publications hereafter received be given to the Boston Medical Library on condition that they be accessible to members of the Society."

The Massachusetts Medical Society assumed ownership of the *New England Journal of Medicine* in 1921, and during the years that the *Journal* staff has occupied offices in the Library building, there has been a close and cordial association. The editor is treasurer of the Library, and the *Journal* deposits its books received for review with the Library.

The intimate association of these two societies appears to have been mutually beneficial during the years, and there seems to be no reason to believe that they should not continue so for many years to come. Indeed, there have been several attempts to a closer relation and even a suggestion of an actual merger of the two societies under the name of an academy of medicine. When these possibilities were more carefully explored it was found that the legal obstacles in the way were insurmountable, largely because of the many trust funds held by the Library for special purposes.

A well equipped and well staffed reference library is an essential branch of medicine both for the

*Presented at the annual meeting of the Boston Medical Library, March 4, 1947

practicing physician and for the research worker. The Library offers its service to all members of the medical profession in Massachusetts, whether or not they are fellows. It occupies the same relation to the physicians of the Commonwealth that a free public library does to the citizens of its community. The citizens support a public library by means of taxes willingly enough, although many of them never use it. They recognize that it is a necessary adjunct to society as a whole. So should the medical profession consider the Boston Medical Library an adjunct to the profession of medicine in Massachusetts and be glad and willing to support it.

It seems logical then that the Massachusetts Medical Society, which represents over five thousand and out of perhaps eight thousand physicians in Massachusetts, should be glad and willing to assume some of the financial responsibility of the Library and thus allow it to put its house in order, enlarge its personnel and offer the reference-library service for which it is otherwise well equipped.

It is a pleasure to report that this has been accomplished. When the Executive Committee of the Council and the Council itself were presented with the facts, they were convinced that the Library could not function as a great library should without the help of the Society. It was therefore voted that \$5.00 out of the increased annual dues be allocated to the Boston Medical Library, with the sole proviso that it be legal and that every member of the Society be made a member of the Library in some category.

Our counsel, who is also counsel for the Massachusetts Medical Society, has rendered an opinion that the Massachusetts Medical Society may lawfully contribute toward the support of the Library. The matter of membership requires some change in the by-laws, and the trustees have authorized me to appoint a special committee to consider this matter. It will be necessary for the fellows to act on any report that may be rendered, and you may expect to be called in special meeting at some time in the near future.

This generous response of the Massachusetts Medical Society will give us next year an added income of over \$25,000. We may lose some fellows, particularly in the nonresident category, but it is hoped that loyalty to the institution and a sense of ownership in the Library will persuade most to retain their fellowships.

So far as plans for the future are concerned, we are fortunate in having the wise and sympathetic counsel of Mr. Keyes D. Metcalf, Director of Libraries of Harvard University. He is intensely interested in our problem, has made a survey of our needs and has offered certain recommendations. I shall leave the discussion of these, for the most part, to our librarian, Dr. Viets. I should like to make a few comments, however.

Mr. Metcalf's first suggestion is to make the Library a first-rate reference collection and, to accomplish this, to weed out unwanted medical and nonmedical books and periodicals and deposit them in the New England Deposit Library. At their last meeting the trustees voted to take this first step without delay. They authorized the Librarian to take space in the New England Deposit Library and to carry out the weeding process little by little during the summer. Books placed in this deposit library will always be available on reasonable notice. This will give us room enough to sort out volumes accumulated in odd places and to place them properly on shelves.

Another necessary undertaking is the completion of the union catalogue of the holdings of all the medical libraries in the Boston area, so that the Boston Medical Library can take its place as the central institution among them. The basis for this catalogue already exists on cards, but the system is far from complete.

We must in the near future give some consideration to the establishment of a pension system for our employees, who, it must be remembered, are not eligible for Social Security benefits.

I hope that we shall be able to put away a little money each year toward the completion of the stacks in the stack building and the elevator to serve them. Five floors of stacks are yet to be completed. Perhaps after we complete our new organization and put our house in order, a special drive for funds should be made for this purpose.

Although there are probably many obstacles in the way of complete realization of our ideals, we are at least embarked on the voyage. I am sure that with the loyal help and support of the fellows, the trustees will give their time and thought to the various problems as they arise to enable us to furnish the type of library service that the Boston Medical Library is well equipped to offer.

WALTER G. PHIPPEN

Report of the Librarian*

IT IS again the privilege of the Librarian to present to the Corporation of the Boston Medical Library his annual report — in this instance, his ninth accounting of the state of the Library. You, as fellows of the Library and owners of the building and its contents, will wish to know whether adequate service has been rendered to our readers, how well the collection has been maintained and what plans are contemplated to carry forward the fundamental aims of the Library in the next few years. The goal in general is the ever-elusive one of complete usefulness to its users, both private and public, of the entire contents of its collections, continually enriched by the addition of treasures from the past and a judicious selection of the medical literature of the present.

SERVICE TO READERS

Both the use of the Library and the attendance increased greatly in 1946 over 1945. The circulation of books reached a total of over 38,000 — an increase of more than 20 per cent. This is nearly the average of the prewar years, for in 1940 and 1941 about 40,000 items were taken off the shelves for our readers each year. During World War II the number fell to about half, indicating how much the Library is used by the younger members of the profession. The same trend is shown by the attendance figures. In 1946 over 10,000 visits were made to the Library. The figure, an increase of 46 per cent over 1945, is about the average for the prewar years.

We thus resumed in 1946 our usual activity both in the number of readers and the number of items that they used. The collection was made available in a satisfactory manner in spite of some delays due to the shortage of personnel. The interlibrary loans more than doubled in 1946, showing that the Library is being used frequently for purposes of research by other institutions. We are thus rendering an excellent service in furnishing material to the Harvard University libraries, the libraries of the Boston hospitals and other institutions nearby, as well as those at a distance. The Library was used by the Newton-Wellesley Hospital, the Rhode Island Medical Society in Providence, Smith College in Northampton, the United Shoe Machinery Company in Beverly, the Winchester Public Library and many others. Our largest interlibrary loan service at present, as it should be, is to the Veterans Bureau hospitals. We have sent books, however, all the way from Bar Harbor, Maine, to Dallas, Texas, and San Francisco, California, and even some interested reader from Myrtle Beach, South Carolina, sought a book that presumably could not be found elsewhere. In the course of the year, our members

used the Library over twenty-five hundred times and on the average took out ten books or journals apiece. The fellows used about 60 per cent of their books in Holmes Hall, and 40 per cent were taken home. There were three times as many visitors as there were fellows, but they used only half as many items. This proportion seems proper and indicates that we are serving our fellows well and, in addition, taking care of the needs of our visitors, mostly students. On the two evenings a week that the Library is open we draw only a small percentage of our total members but a much larger number of visitors.

GROWTH AND MAINTENANCE OF THE LIBRARY

As predicted a year ago, the Library contains over 200,000 volumes, and the pamphlets number 140,000, a collection of 340,000 medical items being thus available to the medical profession in Boston and its vicinity, as well as to scholars throughout the country. The Library added about the usual number of books and periodicals in 1946. A large group of French theses were deposited by the Harvard Medical School Library. As might have been expected after the war years, the number of periodicals taken currently by the Library increased from 578 in 1945 to 723 in 1946. Most of the increase was in foreign-language periodicals, a gain from 44 to 139. We are not up to the record number of journals received in 1937, — namely, 907, — but this is largely accounted for by the fact that only 2 German periodicals were received in 1946. The foreign journals of the war years, 1940–1945, however, are beginning to come in. Early in 1947, the German periodicals for the years 1940 and 1941 were received and many of the Dutch, Scandinavian, Swiss, French and Italian journals from 1940 to 1945 have also been placed on our shelves. Our book dealers in Europe, old and loyal friends of the Library, kept files so far as possible of all medical periodicals, and it was a pleasure again to open packages of large contributions from Nijhoff in The Hague, Le François in Paris, Nardecchia in Rome, Enslin in Berlin and Haus der Bucher in Geneva. An active foreign exchange was continued with the Soviet Union, and about 27 of the current Russian medical periodicals were received, some of these sets are nearing completion. In exchange we are sending standard American medical periodicals to Russia, and later we hope to expand into books and pamphlets. We are also receiving Russian journals from the Harvard Medical School Library, and plans are being worked out to centralize all Russian medical literature in Boston in the Boston Medical Library.

The Library is still falling behind in the binding of its periodicals, only 378 volumes of the 723 periodicals received being bound in 1946. We thus

*Presented in part at the annual meeting of the Boston Medical Library, March 4, 1947.

added to our accumulation of volumes needing binding. The division of current literature, most used by the fellows, should be kept up to a high degree of standard by an increase in the number of periodicals and by the binding of those that are extensively used.

THE FUTURE

The available stacks are overloaded with books and periodicals, volumes and loose numbers of journals and pamphlets have to rest on the floor. To provide for future accessions, we should build the new addition to our stacks immediately or seek room elsewhere for the storage of little-used material. Possibly, the character of accessions should be changed so that fewer books and journals come into the Library each year. Of the solutions proposed to meet our needs, the new stacks seem to the Librarian the most important, and he again calls the attention of the fellows to the great need for building the remaining tiers of the stacks, already so useful in their abbreviated form. The building is ready to house them, and we can probably arrange to get the steel to complete the seven additional tiers.

Another method of lesser value is being employed for immediate relief. Arrangements have recently been made to take over a section of the New England Deposit Library in Cambridge, and this will become available to us on July 1. The New England Deposit Library was established about six years ago under the auspices of Harvard University, and a building erected on Western Avenue in Brighton in the rear of the Harvard Business School. Space in this building is now rented by the Boston Public Library, the Boston Athenaeum, the Massachusetts State Library and other neighbor libraries. More than half the space is used by the Harvard College Library. At present the entire building is filled with books, except for a quarter of one floor. This space has been allocated to the Boston Medical Library and will be fitted with metal stacks built close together in eleven and a half double-faced ranges. A range consists of nine sections 3 feet in width, making a total of 27 feet in length, and each section contains seven, eight or nine shelves, depending on the height of the books. The total number of linear feet available for shelving is about 2000, and on an estimate of eight or nine volumes to a foot, the space will accommodate about 20,000 books. Thus, the little-used material will be available either at the Deposit Library itself or for daily transportation back to the Boston Medical Library. Books and other material designated for the New England Deposit Library will be moved after July 1, for this material has already been partly earmarked and a considerable portion is segregated in boxes piled on top of the present two tiers of stacks in the new stack building. Some books, moreover, will be removed from the old stack room, and by the use

of the Deposit Library, even though our new stacks are not built within a year or two, the Library will be in reasonably good condition so far as shelving in the immediate future is concerned.

What should be the aim of the Boston Medical Library in the future? It cannot continue to develop as a universal medical library, for it has neither the space nor the money. The Library must change its course without, in general, changing the principles for which it was founded. Book-collecting activities should be delimited, and the Library developed into a first-rate working research collection, rather than a universal collection in the field of medicine. Delimitation should be based on three aims certain aspects in book collecting in which the Boston Medical Library should have a strong or inclusive collection, those in which a good up-to-date representation is sufficient, and those in which a comparatively small sampling is all that is needed. The first category consists of strong groups of current medical journals in all languages and from all countries. We should receive more than a thousand current medical periodicals, and provision should be made to bind and house them conveniently on our shelves. In addition, the latest textbooks, monographs and current editions of all sound medical publications should be acquired, particularly in the field of clinical medicine. In the second category, the fields allied to medicine, we should have an up-to-date representative collection of books on chemistry, physics, biology and so forth. We should not expand completely into this field, for books of this type are available at other libraries in or near Boston. Through a mutual understanding and interlibrary loan system, volumes called for in these categories could easily be obtained for our readers. Finally, we need a sampling of the greatest books in medical history. Many of these have already been acquired by the Library, but we should keep up our strong collection of medical history, biography, bibliography, literary medicine, reference books and similar branches so far as our funds permit. There is no reason, moreover, why the Library should not welcome more funds for such a purpose, and the Librarian will certainly not look askance at a medical library of historical interest to supplement the collection along these lines. This, however, would not be the primary interest, and the Librarian does not contemplate turning the Boston Medical Library into an antiquarian society. Because of the impetus given to it in the past, however, because of funds already acquired and because of forces that bring things to a library so well housed and catalogued as ours, he does not worry about the continued care and augmentation of our special collections. Such books are, indeed, the working tools of the medical historian. As scholars learn about our collection of incunabula and other books of rare and important value, the Library becomes more and more used every year for his-

torical research. We are thus attempting to suit the working needs of the scholars of medical history as well as to supply all the needs of the members of the medical profession in Boston and in Massachusetts. Everyday working purposes should set the standards, however, rather than inclusive historical or bibliographic ends.

In addition, we need a weeding-out process. The Library should have had in years past what Osler always termed "an annual shed." Unfortunately, the Boston Medical Library has been primarily acquisitive for over seventy-five years, taking nearly all it could put its hands on and being rather proud of the growing collection. During this process we have not unnaturally added a certain amount of nonmedical material that should be discarded at once, and similar items should not be acquired in the future. Borderline material may be kept by the Library and deposited in the New England Deposit Library, where it is easily accessible when called for.

RELATION WITH THE MASSACHUSETTS MEDICAL SOCIETY

The Library building has long been the headquarters of the Massachusetts Medical Society as well as the repository for our collection. In it are housed the offices of the Society and of the *New England Journal of Medicine*. That these organizations should seek a closer form of co-operation with the Library is not surprising, for the added support of the Massachusetts Medical Society to the Boston Medical Library will give to the medical profession in Massachusetts a proper solidarity not found in any other state in the Union except possibly in Maryland, where the Medical and Chirurgical Society maintains its own library in its own building. Thus, an opportunity is given to interweave the old with the new. All the records of the Massachusetts Medical Society, the early documents pertaining to medicine in the Commonwealth and items of every description regarding the practice of doctors and the lives that they led have already accumulated in abundance in the Boston Medical Library. For over seventy-five years, the Library has been the natural source for the collection and cataloguing of material, and by a gravitational process the libraries of physicians have been bequeathed in large numbers to the Library itself, thus, we have on our shelves a reflection of the past practice of medicine in Massachusetts, a portion of which has already been used in the *History of the Massachusetts Medical Society* and similar publications. The Library will continue to add everything that is pertinent to medicine in Massachusetts, for not only from books but also from manuscripts and private letters of our predecessors can a vivid picture of their lives and the times in which they lived be formed.

To these must be added the old books in medicine, for as Osler said, "Nothing utilizes the new more

effectively than the presence of the old." Our special collections give the same tone to the Library as the portraits of ancestors by Stuart and Copley to the dining rooms of many houses. To the Librarian, all books are old, for nothing ages so quickly as a book. In a decade almost every medical book becomes, indeed, extremely old, and much of the immense literature of the past is not worth shelving, except for historical research, in the Boston Medical Library. We can be grateful that there is an institution in America, the Army Medical Library in Washington, where everything pertaining to medicine can be kept. Theirs is the duty of indiscriminate purchase, ours must be limited to a smaller field, primary consideration being given to the current literature and papers of local interest. Of course, we have had our enthusiasts, who are still welcome and who, for one reason or another, are attracted to a certain class of works, such as incunabula and books on special subjects. Money has been left to us for the purposes of developing these collections, and the Library will never forget its duty. Boston has always had many physicians with the happy combination of literary tastes, leisure and a long purse, and the Library collection reflects the interest of these men as do few libraries of medicine in the United States. Sometimes these interests are expressed in the field of medical medals, portraits, autographs, etchings or bookplates. Here again we should "hold fast to that which is good," for this sort of activity is far from making the Library a dumping ground for unwanted material. There is plenty of that, published mostly in the Seventeenth and Eighteenth Centuries, and the universal collection of material of this type does not fall into our province.

The Library is primarily an educational institution, devoted to the education of the doctor of our time. Every book and pamphlet on our shelves is of interest to someone, but the greatest use of the Library naturally comes with the current literature of all lands and in this we are, indeed, fortunate in the large number of journals, transactions of societies and reports that we accumulate year by year. With the co-operation of the other libraries in and near Boston the Library expects in the near future to be able to make available for the laboratory worker, the specialist and the general practitioner all the current literature that is worth while. Every book and journal may not find a place on the shelves, but should that work be available in Boston or, indeed, anywhere in the United States, the Boston Medical Library will bring it to the doctor's desk or his laboratory table.

In carrying out this idea, the Librarian held an informal conference with the librarians of schools and hospitals in and near Boston on December 7, 1946, to consider matters of mutual interest. Representatives of the Mt. Auburn Hospital Library, Tufts College Medical and Dental School

Library, New England Deaconess Hospital Library, Treadwell Library (Massachusetts General Hospital), Harvard Medical School Library and its departmental libraries, Harvard School of Public Health Library and the libraries of Boston University School of Medicine, Boston City Hospital, Boston Psychopathic Hospital, Beth Israel Hospital, Newton-Wellesley Hospital, Massachusetts College of Pharmacy, Massachusetts Department of

that will benefit all the libraries participating in this conference

ACCESSIONS

The Library has added two medical manuscripts, a number of Sixteenth Century and Seventeenth

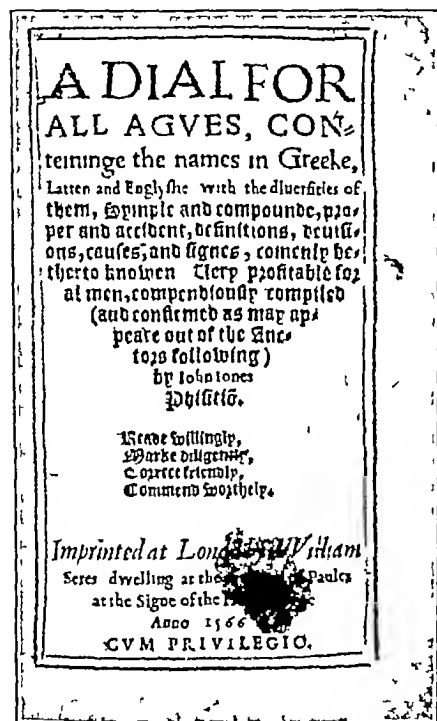

FIGURE 1 Title Page of *A Dial for All Agues*, by John Jones (London 1566)

Public Health and Massachusetts Department of Mental Health met to discuss policies of inter-library loans, the coverage of special fields, exchanges between Boston libraries, the collection of ephemera and related materials and general co-operation regarding the development of the libraries in Boston and its vicinity with special reference to medical, dental and pharmacologic problems. Further meetings of this nature are planned, and there already has been set up a plan for activities

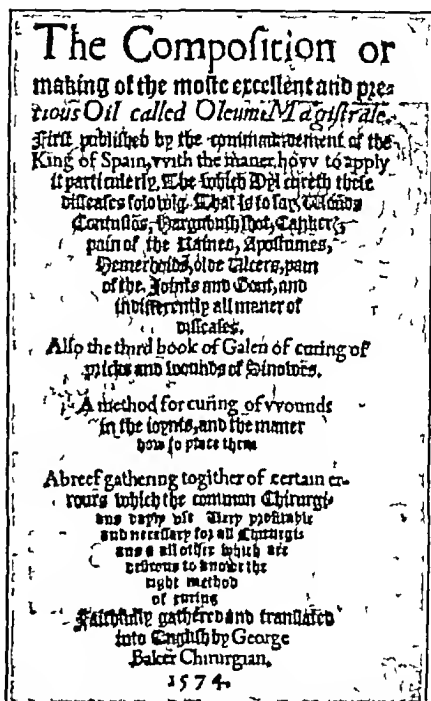

FIGURE 2 Title Page of *The Composition or making of the most excellent and precious Oil called Oleum Magiſtrale* by George Baker (London, 1574)

Century imprints and eight English books, published before 1640. A fine collection of private letters written by Dr Ezekial D. Dodge, and a dozen or more American imprints have also been acquired, including the second edition of *Morton's Letheon* (1846).

Two of our English imprints were acquired through the courtesy of Mr William A. Jackson, of the Houghton Library. *A Dial for All Agues*, by John Jones, a Welsh physician, was published in London in 1566 (Fig. 1). Dr Jones wrote a number of books on fevers, medicinal baths and general health measures. He was a fashionable physician of his

time who practiced in Bath and other parts of England. The title page contains the following quaint admonition "Reade willingly, Marke diligently, Correct friendly, Commend worthely." Other copies of this rare black-letter book are

This active surgeon also translated the works of Conrad Gesner, Guido and Vigo into English. He was a friend of Clowes, the great contemporary surgeon, and of Gerard, the herbalist. Baker is best remembered for his work in writing on learned

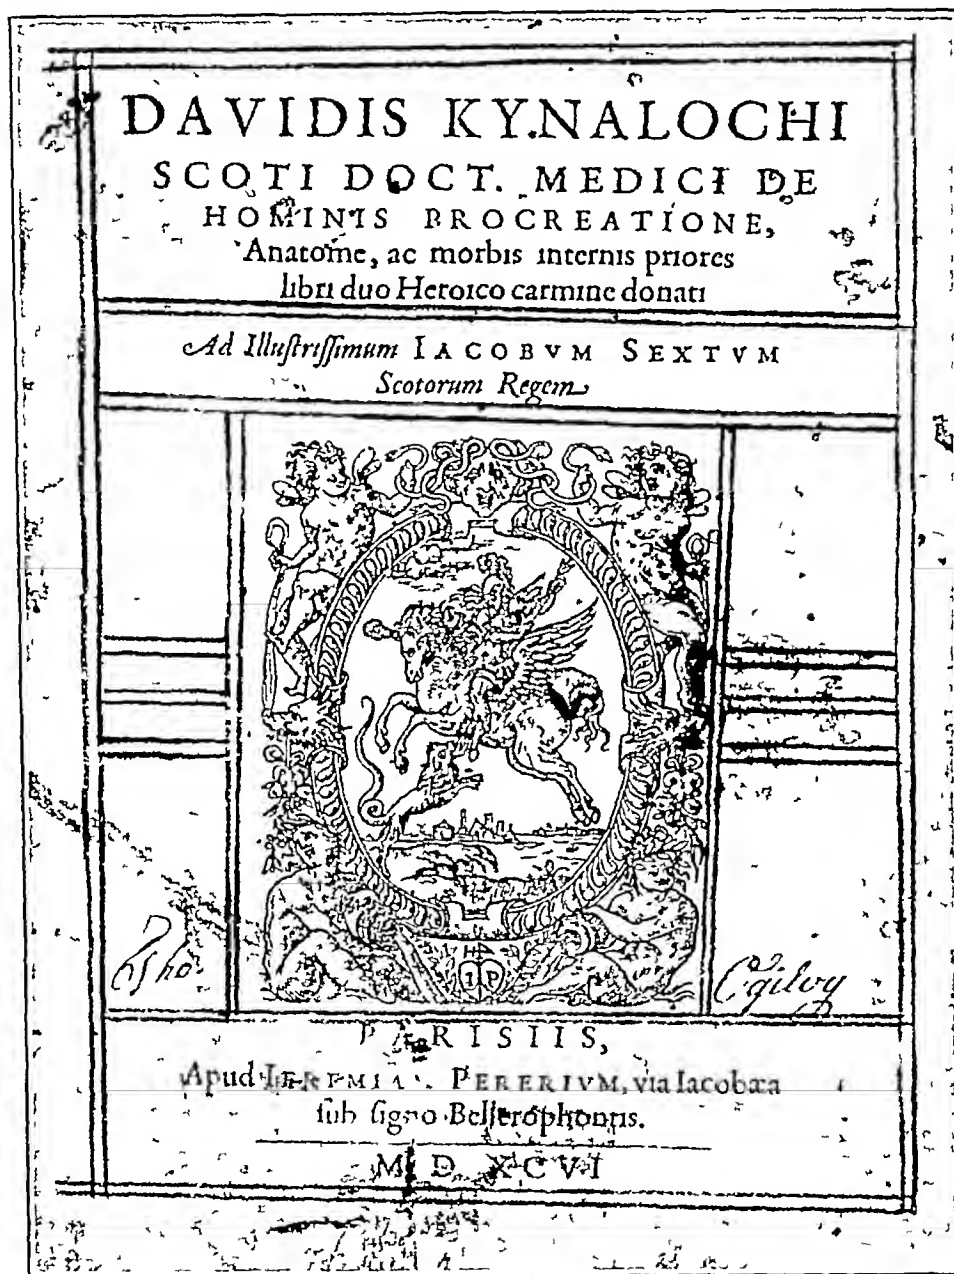

FIGURE 3 Title Page of *De Hominis Procreatione*, by David Kinloch (Paris, 1596)

recorded in the British Museum and the H. E. Huntington Library.

The second book, *The Composition or making of the most excellent and pretious Oil called Oleum Magistrale*, by George Baker, was issued in London in 1574 (Fig. 2). Baker, a member of the Barber Surgeons' Company, was attached to the household of the Earl of Oxford when he wrote on the *oleum magistrale*, a preparation of wine and herbs used for the cure of wounds, ulcers and other diseases.

subjects in the vulgar tongue. Copies of Baker's *Oleum Magistrale* are recorded in the British Museum and Cambridge, England, but not in America.

A third work is a medical poem by a Scottish physician, David Kinloch, *De Hominis Procreatione*, published in Paris in 1596 (Fig. 3). The book is an early text on obstetrics. Little was known of Kinloch until the investigations of R. C. Buist¹ in 1926 disclosed that the author of these Latin verses was born in Dundee in 1559 and probably obtained

his medical degree in Paris in 1596, the year that his book was issued. Like many of his contemporaries, Kinloch was a great traveler. Tradition has it that when in Spain he was seized by the Inquisition and condemned to die. When the Grand Inquisitor became ill, Kinloch's services as a doctor were accepted, and after a cure had been effected, Kinloch was sent home to Scotland.

Finally, a pleasant edition, in Italian, of one of the most popular medical books ever written, *Thesaurus Pauperum* di messer Pietro Hispano, printed in Venice in 1531, was added to our collection (Fig 4). Of the incunabula editions of Peter of Spain's famous compilation, five in Italian and one, the first, in Latin, only single copies are usually recorded in libraries throughout the world. The Boston Medical Library has the fourth edition in Italian, the only example of this printing in America. Some of the other editions, including the first Latin and the first Italian, are available to American scholars in the Army Medical Library. After 1500, more frequent printings of the *Treasury of the Poor* were demanded, since it had become the most popular book of its kind in the Sixteenth Century. This was at least partly due, as Sarton reminds us, to its brevity and to its practical nature. In addition to the 1531 Italian imprint the Library has the first printing in English, issued in London about 1550, and the first Spanish edition of 1532. The title page of the *Thesaurus* of 1531 shows a patient presenting to the physician a bottle of urine for diagnosis. The doctor in turn gives to the patient the appropriate diagnostic slip from a stock of them in a bag at his feet. Peter of Spain—or more accurately, Peter of Portugal, since he was born in Lisbon—was the son of a physician. He studied medicine in Paris and Siena, became a cardinal in 1273 and Pope John XXI in 1276, only to die by accident eight months later. Peter also wrote a treatise on diseases of the eye, many commentaries and a book on logic.

LIBRARY ACTIVITIES

Exhibits

The Library took part in a number of important exhibits in 1946. A special exhibit in the Whitney Museum of Modern Art in New York in October and November and also a continuation of this exhibit at the Museum of Fine Arts in Boston was augmented by our collection of drawings by Dr. William Rimmer. During the centennial of the First Public Demonstration of Ether Anesthesia, held primarily at the Massachusetts General Hospital on October 16, 1946, the "Ether Painting," by Robert Hinckley, which hangs in Ware Hall, was restored, prior to the exhibit at the hospital, through the kindness of our former president, Dr. David Cheever. The most significant parts of our ether

collection were on exhibit in the Treasure Room at the Boston Public Library during October and November.

Gifts

The Library has received many special gifts through the kindness of a wide variety of individuals

FIGURE 4 Title Page of *Thesaurus Pauperum* by Pietro Hispano (Venice 1531)

and libraries. Particularly valuable is a collection of French theses and Dutch and Spanish dissertations received from Harvard Medical School. The Suffolk District Medical Society made a grant of money to the Boston Medical Library in the sum of \$1350. Dr. David Cheever presented a substantial sum for the purpose of restoring the Hinckley picture, and Dr. Dwight O'Hara gave money to encourage the use of the meeting halls in the Boston Medical Library by student organizations.

Meetings

The Director attended a meeting in honor of Miss Marcia D. Noyes, long the librarian of the Medical and Chirurgical Faculty of the State of Maryland, the meeting of the Medical Library

Association held in New Haven, Connecticut, and a meeting of the Honorary Consultants of the Army Medical Library, in Washington. The last meeting was also attended by the Librarian.

Book Reviews

The Library is rapidly getting up to date with book reviews and book notices. These fell behind in the early part of the year owing to the absence of many reviewers in the armed forces and the shortage of space in the *New England Journal of Medicine* for their publication. Toward the end of the year an active endeavor was made to bring this matter up to date, and by the beginning of 1947 the situation was greatly improved. Reviews of some books were not published in the *Journal* for over a year after receipt. It is now expected that reviews, or at least notes on books, can be published within two or three months after the receipt of the item by the *Journal*. Much of this depends on the good will of our reviewers, who should act promptly or return the book to the Library if they are unable to review it. Secondly, an effort is being made to publish reviews promptly in the *Journal*. The paper shortage, however, is still acute, and the editor reports that it may not be possible to find space to publish all the reviews as promptly as desired.

Publications

Recent articles emanating from the Library are as follows:

Seventieth Annual Report of the Boston Medical Library for the Year 1945 40 pp. Boston privately printed, 1946.

Viets, H. R. Nathan P. Rice and *His Trials of a Public Benefactor*, New York, 1859. *Bull Hist Med* 20: 232-243, 1946.

Editorial. First description of rickets. *New Eng J Med* 235: 144, 1946.

Ballard, J. F. *Boston Medical Library Medical Classification*. Part Two—Index. Third edition, revised. 97 pp. Boston privately printed, 1946.

VARIA

We were pleasantly reminded of some chapters in the history of the medical school at Cambridge by the late Sir Walter Langdon-Brown,² who revived our interest in John Caius, William Gilbert, Francis Glisson, William Heberden, Clifford Allbutt and their contemporaries in a series of brilliant papers delivered before the History of Medicine Section of the Royal Society of Medicine and now issued in book form.

Professor G. Grey Turner³ retold the history of the Hunterian Museum at the Royal College of Surgeons of England, and for the first time in detail we learned of the tragic bombing and fire of May 10, 1941, with the loss of many treasures, leaving the main rooms of the building a hollow shell. About two thirds of the total collections were destroyed, but fortunately many of the original Hunter specimens survived along with the great life-size statue of Hunter, which had been encased in stout brickwork. It is cheering to know that the museum will be reconstructed and that John Hunter's work will still be a source of inspiration to medical men throughout the world.

From a sister institution, the Royal College of Physicians of London, comes the belated FitzPatrick Lectures, planned but not delivered in November 1939, and now printed by the College. The story of the medical interchange between the British Isles and America before 1801 was delightfully told by Archibald Malloch,⁴ librarian of the New York Academy of Medicine, in a series of chapters devoted to various regions of America, such as the West Coast, the Colonial States, the West Indies, the Maritime Provinces and Canada. A valuable chapter deals with medical books reprinted in America before 1801.

CLINICAL NOTE

SOLITARY UNICAMERAL CYST OF THE OS CALCIS

CHARLES C. VERSTANDIG, M.D.*

NEW HAVEN, CONNECTICUT

A REVIEW of the literature reveals a surprisingly low incidence of solitary cysts of the os calcis. The most recent report is that of Copelman et al.¹ Only 12 cases are recorded in the literature, of these only 4 were reported by American physicians. The patients in Copelman's cases complained of pain on standing or walking, which was also the complaint in the case presented below. The case

had been in the military service and was receiving disability for bilateral pes planus. He complained of aching in both feet, and there were clinical objective signs of marked relaxation of the longitudinal arches of both feet, as well as extreme pronation of both feet that was more marked on the left.

Röntgenographic studies of both feet in the lateral projections—on weight bearing—revealed a low triangular pattern produced by the head of the metatarsal and calcaneus. A large cystic lesion was observed in the left os calcis that measured 3.5 cm in diameter (Fig. 1). The lesion was large with a sharply margined radiolucent area involving the anterior half of the os calcis. This lesion was of a pyramidal shape, lying parallel with the long trabeculations of the posterior half of the bone. The posterior segment of the cyst extended superiorly as high as the sulcus for the flexor hallucis longus, anteriorly as far as the trochlear process, posteriorly as far as the lateral process of the os calcis and inferiorly as far as the cortical portion of the plantar surface of the bone. The trabeculations of the cystic segment were ill defined, whereas the trabeculae of the posterior half of the calcaneus appeared normal. The cyst seemed to abut on and to expand the inferior and lateral cortex.

FIGURE 1

described by Smith² was believed to be either osteitis fibrosa or a peculiar architectural anomaly. Brailsford³ described a lesion of the os calcis that was identical in appearance with that in the case reported below. Brailsford called the lesion a "triangular area of osteoporosis." Jaffe and Lichtenstein's⁴ survey of the records of the Hospital for Joint Diseases from 1925 to 1942 failed to reveal a single case of solitary unicameral cyst of the tarsal bones analogous to the type that occurs in long tubular bones.

CASE REPORT

A 28-year-old man was referred for roentgenographic studies of the feet in weight bearing position. This patient

*Chief, Department of Roentgenology, Connecticut State Hospital, Middletown; consulting roentgenologist, Meriden Hospital, Meriden; consulting roentgenologist, Veterans Administration.

Solitary cyst of the calcaneus occurs in the same location in every case reviewed—that is, on the anterior, inferior and lateral aspects of the bone. The cyst is of the single type, with a well defined wall.

The appearance in all published cases is identical, but the lesion in the case reported above is probably the largest encountered.

SUMMARY

A single case of solitary cyst of the calcaneus is presented, adding to the 12 cases already reported in the literature.

The cyst always involves the anterior half of the os calcis

As in other cases, the patient complained of pain on walking or standing

MEDICAL PROGRESS

TUBERCULOSIS

JOSEPH D. WASSERSUG, M.D.*

QUINCY, MASSACHUSETTS

THE prolonged and chronic course characteristically pursued by tuberculosis is reflected in the slow progress that is being made in its conquest. The fatty armor that encapsulates the tubercle bacillus has only been dented, not destroyed, by man-made devices. Until some chemotherapeutic or antibiotic agent is found that will penetrate the inner defenses of this hardy microbe, progress in the field of tuberculosis will continue to resemble a series of skirmishes rather than a pitched, decisive battle.

CHILDHOOD TYPE

A clearer concept is developing concerning the so-called "childhood type" of tuberculosis and its relation to tuberculin sensitivity and pulmonary calcifications. Although it has been amply demonstrated in recent years that not all calcifications are due to tuberculosis, the question remains unanswered whether there is a loss in tuberculin sensitivity following the healing of known primary tuberculous lesions. If the primary complex is truly healed, does the child become tuberculin negative? If not, how long does tuberculin sensitivity persist?

To answer these questions Hardy¹ reviewed the records at the Harriet Lane Home Tuberculosis Clinic and selected 312 subjects (born between 1912 and 1930) who had had a primary tuberculous infection in childhood and who had been followed for at least seven years. In this group there were 193 Negroes and 129 Whites. All had had at least one positive tuberculin test, and 87 per cent had known contacts. Follow-up examinations revealed that tuberculin sensitivity was remarkably persistent during the period of study but varied considerably with the degree of infection received in childhood. In subjects who had had primary pulmonary infection, there was practically no loss in the degree of sensitivity, whereas of 171 persons who had had primary mediastinal tuberculosis, 2 per cent became anergic. Of the 82 remaining patients who had had only a positive tuberculin test without any associated roentgenologic findings, as many as 6 per cent be-

came anergic. Thus, the greater the severity of the initial infection, the more persistent tuberculin sensitivity appeared to be. Conversely, it is likely that if calcifications are present and the tuberculin test is negative, tuberculosis is not responsible.

Another study, by Edwards and Hardy,² reveals that the degree of tuberculin sensitivity bears some relation to the prognosis. In 34 children who were relatively insensitive—that is, with reactions to not less than 1.0 mg of tuberculin before their third birthday—there were no deaths, and no patients developed pulmonary calcifications or extrapulmonary lesions. There were no deaths in a group of 26 children who reacted to 0.1 mg of tuberculin, but 3 patients showed subsequent calcifications on x-ray examination of the chest. In sharp contrast, in the highly sensitive group of 103 children who reacted to 0.01 mg of tuberculin, 43 per cent had non-calcified parenchymal lesions, 62 per cent developed intrathoracic calcifications and 14 per cent died. Of 44 infants who gave vesiculate reactions to 0.1 mg of tuberculin, 50 per cent developed parenchymal lesions, 77 developed intrathoracic calcifications and 16 per cent died. Thus, the degree of sensitivity in childhood may serve as a rough guide to the prognosis—the less sensitive the response, except, of course, in moribund patients, the better the prognosis.

The age of the patient at the time of infection also seems to bear a significant relation to the prognosis. The opinion of Kendig and Hardy³ is as follows:

The infected infant may be able to overcome tuberculous infection if the adult contact can be promptly removed. If, however, the contact remains and the baby is subjected to a constant opportunity for more infection, there is much greater likelihood of a serious, or even fatal, outcome.

It is wise to assume, therefore, that all subjects who show a positive tuberculin test before the age of three years have active infection. In such children, indeed, the infection has hardly had time to become inactive. More light on these problems may eventually be shed by the plan of study suggested by

*Instructor in medicine, Tufts College Medical School

Biggs,⁴ in which x-ray and clinical investigations are correlated

Arrest of disease in childhood, as indicated by a calcified primary complex, may denote a truly healed lesion in the sense that the calcified lesions are no longer infective. To determine how frequently viable bacilli could actually be recovered from the primary complex of children dying of other causes, Feldman and Helmholz⁵ collected material from 29 cases over a period of six years and inoculated the specimens into guinea pigs. In only 5 cases were viable, virulent tubercle bacilli demonstrated by the tests. The authors state

The failure to demonstrate the presence of living tubercle bacilli in 24 of 29 patients having childhood tuberculosis provides reasons for support of the belief that sensitivity to tuberculin in children may be transitory and that, in children whose tuberculosis is limited to the lesions of the primary complex, the continuation of the sensitivity to tuberculin is probably related to the infectivity of the tuberculous foci.

The age at which infection occurs appears to have a direct relation to the development of calcifications. High and Zwerling⁶ studied 198 American-Indian children who developed tuberculosis while under observation and in 49 of whom calcifications later developed. Deposits of calcium were noted one to four years after the appearance of the lesion, usually during the second and third years. More than three fourths of the youngest patients developed calcifications, whereas calcium deposits were detected in only 2.4 per cent of the cases in which the onset of the disease was between the ages of fifteen and nineteen years. The presence of demonstrable pulmonary lesions appeared to influence the subsequent development of calcifications. One fourth of the patients who had pulmonary lesions subsequently showed calcium deposits. On the other hand, in cases in which tuberculin conversion was not accompanied by any demonstrable lesion, calcium appeared in only 2.2 per cent.

Although tuberculosis is extremely serious in infancy, the disease is relatively mild later in childhood. It is also true that the treatment of children with a primary complex, such as that afforded by a sanatorium, has no effect on the development of progressive tuberculosis in later life. Most competent investigators therefore believe that mass examination of children in grade schools should be abandoned.⁷ High-school students can be examined more profitably, but, as Pope⁷ points out, there is still some controversy regarding whether routine screening by the tuberculin test is desirable. Much, he says, depends on the region in which the tests are being done and on the type of x-ray equipment used. A final diagnosis of tuberculosis, however, should not be made on the first x-ray film, since a disturbing number of cases showing definite infiltrations of the lung fields will be found to have cleared completely on a re-examination two weeks later.⁷ Although mass examination of high-school students for tuber-

culosis is popular with parents and school authorities, Pope suggests that general hospitals, industrial plants and mental hospitals are more profitable fields for discovering new cases.

The precise role that should be assigned to the tuberculin test in case finding is still a matter of dispute. Myers⁸ has advanced persuasive arguments for routine tuberculin testing of all children, as well as adults, and has cited considerable evidence for its value in controlling tuberculosis in the Minneapolis area. "Twenty-five years ago, the tuberculin test was believed to be only applicable to children, but experience has taught that it is of great value in testing persons of any age." According to his point of view, any person reacting to tuberculin has tuberculosis just as certainly as the patient who is dying from the disease, the only difference being one of degree. Hilleboe⁹ has prudently prefaced Myers's statements with the notation that this point of view is at variance with the conclusions of some other workers in the field. Tice,¹⁰ of the Chicago Municipal Tuberculosis Sanatorium, presents a somewhat different approach to the problem.

CONTROL

Although the x-ray apparatus detects pulmonary lesions more readily than the stethoscope, chest roentgenology has not yet advanced to the point where it can be substituted for logic or reasoning. Diagnosis is a function of logic, and the diagnosis of chest diseases, especially tuberculosis, depends on the correlation of clinical, roentgenologic and bacteriologic studies. No x-ray machine can do this. The diagnosis of tuberculosis or its degree of activity should never be based wholly on the x-ray report of the chest findings. "Never put your complete trust in shadows" is a sound medical adage that applies especially to tuberculosis.

Probably the most notable advance in the past year lies in the growing awareness of the fallibility of the x-ray machine and its limitations in the diagnosis of tuberculosis. Certainly, x-ray findings, alone, must never be used to determine the disposition of the patient. The chief exponent of this thesis is Hilleboe,¹¹ whose remarks should be compulsory reading for every physician who has occasion to send a patient to the sanatorium. He contends that many persons have been labeled as tuberculous wholly on the basis of the x-ray findings. "This is scientifically unsound," he says, "and damage is done to people and to control programs." A patient with suspicious x-ray findings should, at least, have a complete history, a physical examination and sputum studies before the x-ray findings are tagged with a specific label. "Let treatment be delayed," urges Hilleboe, "until all the facts are in and all the evidence is evaluated." Persons who have tuberculosis that requires sanatorium care cannot be greatly harmed by a short delay of treatment, in many cases the disease has been present

for some time. Even those whose diagnosis is confirmed will profit by a period of waiting, during which they may become accustomed to the idea of having a serious disease. Similarly, in my opinion, the sending of a person who does not have tuberculosis to a sanatorium is tantamount to imprisonment without a fair trial. Worse still, it may expose a susceptible person — especially one who is tuberculin negative — to possible infection.

Other authorities agree that clinical conclusions drawn hastily from x-ray films are dangerous. A recent exhaustive report¹² emphasizes the fact that the personal equation enters significantly into the interpretation of chest films so that one man may read tuberculosis on a film at one time and may call the same film normal when it is reviewed.¹² The variation in interpretation among several observers is even greater. Shepard¹³ also cautions against overlooking some of the limitations of the mass x-ray survey.

We should not refer to the x-ray as the one and only way to diagnose tuberculosis. Even 14-by-17-inch stereoscopic plates will not provide a sure diagnosis, much less a single miniature film. Positive diagnosis of tuberculosis is a long, complicated, highly skilled process. The x-ray is but a part of this process.

All the roentgenologist can and should do is to describe the type of shadows cast on the film, since shadows identical with those of tuberculosis may be cast by many diseases. Diagnosis should rest with the clinician, not the roentgenologist. In this connection, Rest¹⁴ has cited many cases in which nontuberculous pulmonary conditions have been diagnosed as tuberculosis on the basis of the x-ray and the clinical findings. In every case, however, examination of the sputum was negative.

If there is so great a liability of diagnostic error in the routine mass x-ray surveys and even in the standard 14-by-17-inch films, it is difficult to understand how miniature photofluorography of the clothed subject can fail to add considerably to the existing confusion. Nevertheless, the experience of Lewis¹⁵ indicates that, for mass surveys only, photofluorography of the clothed subject is without objection and that it has the advantages of speed of operation and reduction of space and personnel. Lewis, however, admits that this approach to the problem may be productive of a "narrow margin of error."

The general practitioner has often been glowingly referred to as the "keystone" in any tuberculosis-control program and, at the same time, has often been criticized for failing to put the full weight of his authority behind government-planned surveys or other publicly sponsored control measures. Too often, according to Hilleboe,¹⁶ the control of tuberculosis is assumed to be the responsibility of the health department alone. Yet how can the assumption be otherwise when more and more of the physician's responsibility of diagnosis and treatment is being taken over by public-health authorities? How

often, indeed, is the general practitioner asked to sit in the councils where tuberculosis programs are planned? Neither the state agencies nor the voluntary agencies seem to look to the practitioner for an opinion.

During the past decade or two, it seems to me, there has been a progressive narrowing of the opportunities available to an intern or resident — the future practitioner — to acquaint himself with the diagnosis and management of tuberculosis. General hospitals often prohibit the admission of tuberculous patients. Other hospitals provide only interim care until admission to a sanatorium can be arranged. As a result, training in tuberculosis is often inadequate and a quasi-conditioned reflex has been created among physicians so that the mere mention of the word "tuberculosis" carries an instantaneous connotation of "sanatorium." Lack of responsibility in the care of these patients during the period of training gives the physician a sense of insecurity both in diagnosis and management. Consequently, it has been necessary recently for public-health authorities to compile a guide for the physician in the disposition of persons with abnormal x-ray findings.¹⁷ As valuable as this guide is, it is no substitute for the confidence gained from experience that a physician should have in the handling of all patients. To the dictum of Hilleboe and Holm,¹⁷ "Do not diagnose pulmonary tuberculosis on the basis of an original x-ray film alone," should be added the corollary, "Not every patient with tuberculosis has to be in a sanatorium." Practically, all such patients can be studied at home, and some, if conditions are favorable, can be treated under the general practitioner's care with, perhaps, occasional advice from an expert. Only then will the general practitioner be an active participant in tuberculosis-control programs.

In spite of these considerations, it is gratifying to report the continuing decline of tuberculosis mortality. To those interested in some of the statistical aspects of tuberculosis control, the reports of Pitney and Kasius^{18, 19} are recommended. The world-wide situation regarding tuberculosis prior to the war is briefly discussed and summarized by Yelton.²⁰

BACTERIOLOGIC CONSIDERATIONS

Dubos and his associates^{21, 22} have continued their researches on the growth of tubercle bacilli. Although tubercle bacilli are among the least exacting of pathogenic micro-organisms in their growth requirements, it is often difficult to initiate the growth of small inoculums in vitro. Furthermore, multiplication may be slow, even in some enriched mediums. Dubos and Davis²¹ make the following observation:

These characteristics render difficult the application to tubercle bacilli of a quantitative bacteriological method based on enumeration of living cells by plating or dilution techniques, they delay and at times prevent bacteriological diagnosis of tuberculosis, they hinder investigation concerned with pathogenesis, immunity, and chemotherapy.

Any technic providing for rapid growth and growth of small inoculums would therefore benefit many fields of investigation

Such a technic appears to have been devised by Dubos and Davis,²¹ who describe a modification of Kirschner's medium that is easy to prepare, as well as stable, and favors the growth of small inoculums. In such a medium, the growth-stimulating effect of certain synthetic water-soluble lipids—consisting of esters of long-chain fatty acids—is readily demonstrated. All these stimulating compounds possess both lipophilic and hydrophilic properties, and of these, the product marketed as "Tween 80" (the water soluble ester of oleic acid) was found to be the most satisfactory and the most reliable in its behavior. In the presence of such water-soluble esters the mycobacteria grow diffusely throughout the liquid medium rather than as a surface pellicle. Most important to the clinician is the fact that positive human sputums—after treatment with sodium hydroxide—inoculated into such mediums yield typical diffuse growth. Significant, too, is the fact that high agglutination titers for these new types of culture have been observed in some human serums.²² The usefulness of these researches in the study of the immunologic response in tuberculosis is apparent.

Further investigation along some of the lines indicated above has been carried out by Foley²³ and Youmans.²⁴ At the Massachusetts General Hospital, Foley utilized the depth-growth technics for recovery of tubercle bacilli in the examination of pathologic material sent routinely to the laboratory. An excellent correlation was obtained between the cultural results and those found on guinea-pig inoculation, especially when a small amount of human or bovine serum albumin was added to the culture medium. The incubation period in these cultures ranged from five to twenty-seven days, with a mean of eleven days, in sharp contrast to the period of eight to twelve weeks often required for diagnosis by guinea-pig inoculation. "This preliminary study," comments Foley, "suggests that with reasonable care in their use, these new synthetic media can be invaluable in the laboratory diagnosis of tuberculosis."

Youmans,²⁴ on the other hand, has used depth-growth technics not for diagnosis but to study the culture cycle and growth rate of the tubercle bacillus. The growth curves so obtained showed either a lag phase, such as that obtained with other bacteria, or curves of direct growth not preceded by any lag. Such curves are especially valuable in that they afford the investigator a method for determining the degree of inhibition of various bacteriostatic substances. For example, by this technic it could be demonstrated that, in suitable concentrations, para-aminobenzoic acid could reverse the bacteriostatic action of 4,4'-diaminodiphenylsulfone. On the other hand, para-aminosalicylic acid appeared to be

highly bacteriostatic *in vitro* and at least moderately effective for the suppression of tuberculous infection in white mice.²⁵

An interesting sidelight to the bacteriologic diagnosis of tuberculosis lies in the fact that false acid-fast organisms may be obtained from some wounds to which fats and greases, such as lanolin and petrolatum, have been applied. Saprophytic diphtheroids present in the wound may become coated with such fats, presenting an almost typical acid-fast appearance when stained by the usual methods and viewed under the microscope.²⁶ The nature of the acid-fast stain itself has been further elucidated by Lamanna,²⁷ who postulates that the basis for the acid-fast property lies in the greater solubility of the phenol and dye in the cell constituents than in the decolorizing agent.

THERAPY

Antibiotics

Unlike other chemotherapeutic agents and antibiotics that have had their day of popularity and have quickly gone into discard, streptomycin continues to be a drug of promise in the treatment of tuberculosis. Although Corper and Cohn²⁸ believe that, on the basis of experiments *in vitro* and *in vivo*, there is no evidence that streptomycin enters the important organs in appreciable amounts for any significant time and that the drug is not tuberculocidal in reasonable amounts, they also believe that this antibiotic does retard the growth of actively multiplying tubercle bacilli. "In the usual case of clinical tuberculosis in man, the bacilli appear to reproduce and develop only at irregular periods undeterminable by clinical means and over long periods of time, and this markedly reduces the applicability of a retardant without tuberculocidal action for use in human tuberculosis." Although its application to human tuberculosis is therefore limited, streptomycin may indicate the selective tuberculocide through laboratory experiments.

Clinical reports, however, indicate that streptomycin is effective in the control of tuberculosis. Hinshaw and his colleagues,²⁹ in a study of 75 tuberculosis patients, report that the drug has a "suppressive action" in man but add that long study will be required to determine its optimal dosage and the duration of treatment in various clinical situations. Of 10 patients with generalized hematogenous tuberculosis with or without meningitis, 4 (with meningitis) recovered after streptomycin therapy, clinical findings, however, indicated that the infection had persisted, and the long-term prognosis appeared uncertain. Of 24 patients with pulmonary tuberculosis—14 far advanced, 8 moderately advanced and 2 minimal—19 improved with sufficient promptness to make it appear probable that treatment with streptomycin was a significant factor. All of 6 patients with ulcerating lesions of the major respiratory passages responded rapidly to a com-

bination of streptomycin aerosolization and intramuscular injections. On the other hand, only 8 of 14 patients with urogenital tuberculosis gave a favorable response to treatment. In most cases the total daily dose varied from 1 to 3 gm.

Pfuetze et al.³⁰ also report a series of 30 cases of pulmonary tuberculosis in which streptomycin was administered from two to six months. With few exceptions the patients selected for antibiotic therapy had tuberculosis that was progressive or had not responded to rest in bed. Of these 30 cases, 20 were far and 8 moderately advanced, and in 2 the disease was minimal. On the basis of roentgenographic findings, there was marked improvement in 13 cases, moderate improvement in 7 and no change in 4. Within three to six months after the administration of streptomycin had been stopped there was some exacerbation of the disease in 7 cases, indicating that the action of streptomycin was merely suppressive, not tuberculocidal. In a case of tuberculous meningitis reported by Krafchick³¹ complete clinical recovery was obtained with absolutely no residual neurologic abnormalities.

Some of the limitations of antibiotic therapy have recently been outlined by Hilleboe³² as follows:

It should be kept in mind that any antibiotic, even though effective against the tubercle bacillus, may be of little benefit to far-advanced cases, because irreversible processes have set in and, in most instances, the blood supply to areas of cavitation and other areas with extensive involvement has been cut off.

Too much help should not be expected from an antibiotic in such advanced cases, even though its action is most favorable in minimal disease.

Some other antibiotic, or a combination of an antibiotic and chemotherapy, may prove ultimately to be the actual solution of tuberculosis management. Marshak,³³ for example, has found that California Spanish moss (*Ramalina reticulata*) can be treated chemically to yield a crystalline substance that is nontoxic for guinea pigs and appears to retard the progress of the disease in experimental infections. The possibilities of this compound in human tuberculosis remain to be explored. Smith and his colleagues³⁴ have adduced experimental evidence that Promin and streptomycin have a synergism that enhances the antituberculosis action of each. The possible value of such a combination of drugs in human tuberculosis is also unknown at present.

Chemotherapy

A relatively new bacteriostatic agent, glycerite of hydrogen peroxide, has been described by Brown and Slanetz³⁵ as having tuberculostatic action in a weak dilution (0.1 per cent) and tuberculocidal action in a greater concentration (from 0.5 to 4.0 per cent). After local application in 4 cases to "cold abscesses" of the chest wall and other areas, complete healing was noted in 3 and improvement in 1. Since glycerol,

itself, may inhibit the growth of tubercle bacilli,³¹ however, and since cold abscesses occasionally heal spontaneously, controlled trials with this new bacteriostatic agent must be carried out before its role in the therapy of clinical tuberculosis can be ascertained.

The relation between chemical structure and tuberculostatic activity is of fundamental importance for the future development of more effective tuberculocides, but this relation is still not clearly understood. In vitro tests, however, by Youmans and Doub³⁶ on fifty-nine different sulfone compounds indicate that two para-oriented free amino groups are essential for maximum activity in the diaminodiphenylsulfone grouping. Thus, p,p'-diaminodiphenylsulfone is most active compared to compounds in which a methyl group has been substituted for amino or in other compounds in which the amino radical has been transferred to the meta or ortho position. A new class of tuberculostatic substances, unrelated to the sulfones, has recently been described by Feinstone.³⁷ The parent compound is 5-amino-2-butoxypyridine, but the sodium formaldehyde bisulfite derivative is least toxic. Some strains of tubercle bacilli were inhibited in dilutions as high as 1:100,000,000. The most striking attribute of these compounds is that they appear to be specific for the acid-fast group of organisms and have little inhibitory action on other bacteria.

IMMUNIZATION

In an earlier review attention was called to the increasing recognition being given to BCG (*Bacillus Calmette Guérin*) as a possible immunizing agent in selected persons.³⁸ This year, further evidence regarding its possible value has been presented. Obviously, patients who are already infected, indicated by a positive reaction to tuberculin, are not suitable candidates for BCG immunization.

The experience of the National Research Council of Canada with BCG immunization in hospitals and sanatoriums of Canada has recently been recorded by Ferguson.³⁹ Nurses entering training between 1934 and 1943 were accepted for this study, and in this group, there were 1005 vaccinated subjects, 759 who were initially Mantoux-negative and not vaccinated and 278 young women who were tuberculin positive. Of the vaccinated persons only 9 developed "manifest tuberculosis," — that is, either pulmonary tuberculosis demonstrable by x-ray study or non-pulmonary disease, — an incidence of 0.9 per cent. Of the tuberculin-negative, nonvaccinated nurses, 29, or 3.8 per cent, developed tuberculosis. And of those who were initially tuberculin positive, 3, or 1.1 per cent, had demonstrable disease. Ferguson therefore considered the use of BCG vaccination in the hospital environment to have reduced manifest tuberculosis among negative reactors by three-fourths. Vaccination with BCG was regarded as a safe, practical, convenient and reasonably effective

method of controlling tuberculosis among young women in a tuberculous environment.

In Brazil, where the mortality rate from tuberculosis is about 250 per 100,000 population, the world's most extensive trials with BCG vaccination have been carried out. The Brazilians prefer to use an oral vaccine instead of an intracutaneous vaccine, such as that employed in Canada. More than 340,000 persons have thus been vaccinated, and the results, to date, are regarded as favorable. The details of the program are described by Bueno.⁴⁰

The Danes have also found that BCG vaccination can be carried out safely and effectively. In

MISCELLANEOUS TOPICS

Psychosomatics

With the renewal of interest in psychosomatics generally, a revival of interest in the psychosomatic factors in tuberculosis was inevitable. That this is actually a revival and not something new is pointed out by Friedman and his co-workers.⁴² At the Bronx General Hospital they studied 100 male tuberculous patients, each of whom was given at least a one-hour interview by a neuropsychiatrist. Family data and personal and social histories were obtained and carefully tabulated and evaluated. On the basis of

TABLE 1 Results of BCG Vaccination in Denmark

GROUP	MEDICAL STUDENTS			OTHER UNIVERSITY STUDENTS		
	TOTAL NO	POSITIVE X RAY FINDINGS ONLY	X RAY SPUTUM	TOTAL NO	POSITIVE X RAY FINDINGS ONLY	SPUTUM
Mantoux positive	936	12	6	1135	5	4
Mantoux negative	322	38	17	541	14	4
BCG vaccinated	112	0	0	63	0	0

Denmark all children who are Mantoux negative and all newborn infants in a tuberculous environment are vaccinated intracutaneously. On converting to a positive tuberculin reaction, these children and infants have been permitted to associate with the source of infection at home. In Denmark, therefore, BCG vaccination has been subjected to a severe test, and its general acceptance in that country has been based on truly critical appraisal. For example, Table 1, based on an article by Holm,⁴¹ sums up some of the experience with BCG vaccination among college and medical students, who, respectively, are considered "especially exposed" and "not especially exposed" to tuberculosis. Both the hazard of placing a tuberculin-negative person in a tuberculous environment and the significant degree of protection afforded by BCG vaccination are demonstrated. The greatest incidence of infection was among the tuberculin-negative persons placed in a tuberculous environment. Although the numbers are too small for statistical conclusions the vaccinated persons appear to be the best protected against tuberculosis. Other evidence for this point of view is provided by the Danish experience on the island of Bornholm, where the number of new cases of tuberculosis in the group from fifteen to thirty-five years of age has been reduced by half since the introduction of BCG vaccination. Holm's conclusion is as follows:

The vaccination gives considerable but not absolute protection. It protects completely against the morbid phenomena accompanying the tuberculous primary infection and it also affords a considerable protection against genuine tuberculosis of the various organs — in particular against phthisis.

this and other information it was concluded that the patients with tuberculosis had many personality traits in common.

These patients showed independence and efficiency which made them normally or better than normally adjusted in their economic, sexual and social spheres. They showed some resentment toward authority. They showed obsessive and compulsive characteristics and were optimistic individuals.

Since these data apply only to a limited group of persons — young men — conclusions regarding the personality make-up of other tuberculous patients are not warranted. The authors, however, make certain useful suggestions concerning how these traits may be directed toward purposeful and healthier channels.

Another interesting study, but one that I regard as carrying psychosomatics too far into the realm of infectious diseases, is presented by Hartz,⁴³ who tends to link the dyspnea following thoracoplasty to claustrophobia. The article is valuable in pointing out that psychic reassurance after a thoracoplasty — and perhaps after any major operation — may be as valuable as sedatives and narcotics. Even in tuberculosis one should always remember that the patient, not merely his lungs, needs treatment.

Pulmonary Lavage

Recent reports from Brazilian investigators indicate that pulmonary lavage as a means of recovering tubercle bacilli warrants further investigation. De Abreu⁴⁴ has performed such lavages in 150 cases and considers the technic both efficient and safe. Collection of the sputum is carried out in much the

same way as the pharynx is anesthetized for bronchography, and a cough reflex is then promoted "Pulmonary lavage," says de Abreu, "is yet at the beginning of its application. It is a new method which needs long observation to determine definitely its harmlessness and efficiency." Bueno⁴⁵ believes that his technic, which is slightly different from de Abreu's, is easier to perform than gastric aspiration but that it should not be employed in a person who has a low vital capacity or is suffering from asthma.

Immobilization of Both Lungs

During the past few years Barach⁴⁶⁻⁴⁹ has devised a pressure chamber in which a patient may be placed and allowed (perhaps "forced" would be a better word) to breathe while the chest is completely immobilized. In a recent paper the physiologic principles, the technic and the results of this method are reviewed.⁴⁹ Of a small group of patients, 2 showed no benefit, 3 had moderate or temporary benefit, and 5 had marked benefit or clinical recovery. Although Barach appreciates the difficulty in evaluating any new therapy for pulmonary tuberculosis, his observation is as follows:

The provision of local lung rest by residence in the immobilizing pressure chamber promotes the process of healing and closure of cavity in some cases of advanced and moderately advanced pulmonary tuberculosis. This favorable response has been observed in cases for whom no other form of treatment was possible or who had been exposed to other types of tuberculosis therapy without benefit.

Ambulatory Pneumothorax

It is perhaps not widely enough realized that ambulatory pneumothorax may be used as a valuable adjunct to other measures for the control of pulmonary tuberculosis. Rest⁵⁰ comments on the futility of trying to admit every tuberculous patient into a sanatorium, since there are only 90,000 beds to accommodate the 500,000 known active cases in the United States. If for some reason, a patient cannot or will not be admitted to a sanatorium, ambulatory pneumothorax may be indicated. Good results are reported in a small number of patients who were given this form of therapy, but Rest cautions, "Delay in administering therapy while the patient is still in the treatable stage may alter the prognosis to an unfavorable one and result in years of prolonged sanatorium care for the patient." Tice¹⁰ has reviewed the Chicago experience with ambulatory collapse therapy and has outlined its growth since 1931. He points out that with ambulatory pneumothorax 76 per cent of the patients treated were living, as compared with 39 per cent of the controls. As of January 1, 1945, there were 1600 patients under therapy, 150 under observation for collapse, and 50 under post-treatment supervision. In China, where hospital facilities are woefully inadequate and living conditions wretched, Wright⁵¹ also commented that, although ambulatory pneumo-

thorax was not an ideal form of treatment, there was obviously a great need for the method under such conditions.

Bronchography

Further recognition should be given to the fact that bronchography, which is widely used in the diagnosis of bronchiectasis, may be carried out with safety in tuberculosis. Boyer⁵² points out that whereas bronchography should not be used as a routine procedure in tuberculous patients, it is often of value in revealing the source of positive sputum. This is particularly true in cases in which thickened pleura, empyema and thoracoplasty obscure the pulmonary pattern. Reference should also be made to the exhaustive investigations by Dormer and his colleagues⁵³ on this subject.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C CABOT

TRACY B MALLORY, MD, Editor

BENJAMIN CASTLEMAN, MD, Associate Editor

EDITH E PARRIS, Assistant Editor

CASE 33271

PRESENTATION OF CASE

A sixty-one-year-old mechanic entered the hospital because of epigastric pain.

He had apparently been in good health until seven years before entry (two months before the death of his wife), when he began to have episodes of pain in the right and middle epigastric region. He was treated conservatively for several months at a clinic and then sent home with instructions to rest, to stop smoking and to drink milk whenever he had pain. He remained asymptomatic for six months, but when he returned to work and started to smoke again the pain recurred. During the six years before entry he had pain almost daily. It was not entirely relieved by food and was usually worse about two hours after eating. Amphogel and milk were of some benefit. For six months before entry the patient had had gaseous eructations, nausea and occasional vomiting, as well as increased epigastric pain. He also complained of severe

spontaneous epistaxes, which had occurred during the eight months before entry. There had been no hematemesis or changes in bowel movements. The patient believed that he had recently lost weight but did not know how much. He denied drinking alcohol but admitted smoking twelve to fifteen cigarettes a day.

Physical examination disclosed a well nourished patient in no distress. The heart and lungs were clear. The abdomen was tense, with a sense of resistance in the epigastrium and right upper quadrant. The liver edge was percussed two finger-breadths below the costal margin in the midaxillary line. There was no abdominal tenderness.

The temperature, pulse and respirations were normal. The blood pressure was 148 systolic, 90 diastolic.

Examination of the blood revealed a red-cell count of 5,500,000, with 18 gm of hemoglobin, and a white-cell count of 7300, with 68 per cent neutrophils. The urine was normal. A stool was soft, yellow and guaiac negative. The total protein was 7.0 gm, and the nonprotein nitrogen 28 mg per 100 cc, and the chloride 104 milliequiv per liter. The prothrombin time was normal. A blood Hinton test was negative.

A gastric analysis revealed 40 cc of pinkish, mucoid material with no free hydrochloric acid before the administration of histamine. Thirty minutes after histamine had been given 30 cc. of similar fluid contained 30 units of free hydrochloric acid. A gastrointestinal series revealed an ulcer crater, 2 cm in breadth and 1 cm in depth, lying along the lesser curvature high in the fundus just below the esophageal orifice. No definite tumor mass was seen about the ulcer. Barium

passed the pylorus without hesitancy, filling a duodenal bulb to normal contour. On the seventh hospital day gastroscopy revealed a reddish, hyperemic area high in the lesser curvature. This area seemed to extend into the fundus but could not be completely visualized. Elsewhere the gastric mucosa appeared normal. No ulcer was seen.

A smear of gastric juice was reported "negative" for malignant cells. The patient continued to have

somewhat long for a neoplasm. It is implied by the history that the onset of difficulties occurred at a time of great psychic stress. The therapeutic regimen prior to hospital entry was apparently poor. It has been my experience that a patient with a peptic ulcer often receives instructions or advice from his physician to take between-meal antacids or food only at times when pain is present. A proper program is obviously one that prevents

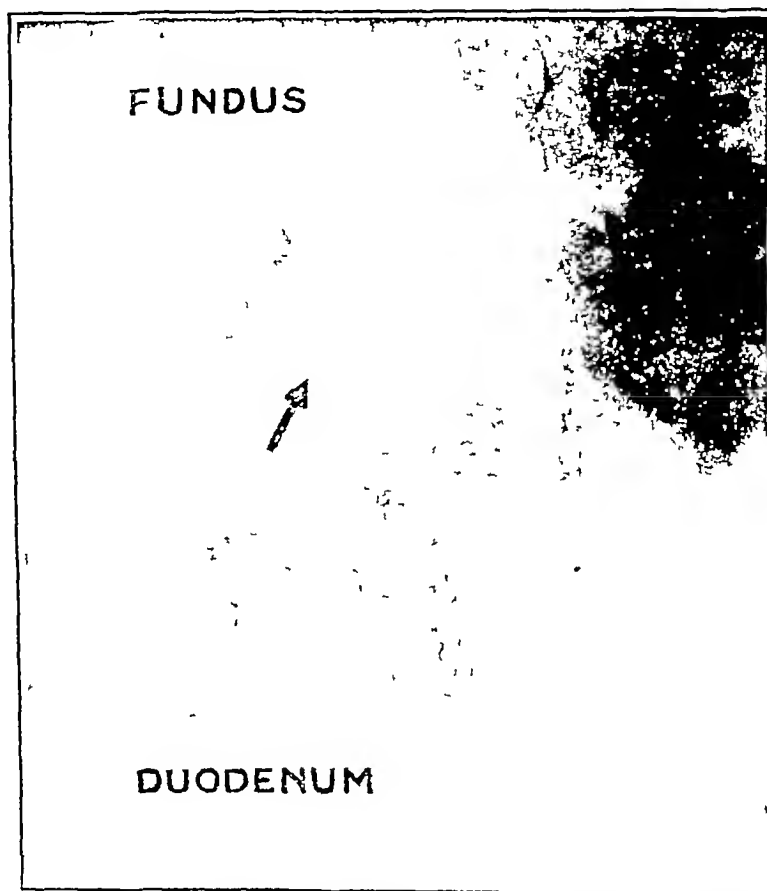

FIGURE 1 *Roentgenogram showing Gastric Ulceration and Surrounding Mass*

pain two to four times in twenty-four hours, usually at night. At times the pain lasted throughout the day and failed to respond to milk and Gelucil. Another gastrointestinal series during the third week showed no change in the size of the ulcer (Fig 1).

On the twenty-seventh hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR WADE VOLWILER. This case presents the problem of the differential diagnosis between benign and malignant peptic ulcer, located high on the lesser curvature of the stomach immediately below the esophageal entrance. The duration of the symptoms, all of which supposedly occurred from this particular lesion, was seven years, which seems

such pain from occurring by regularly scheduling the medication and food by the clock. After a brief remission the pain syndrome in this case returned when the patient returned to work and to smoking. It is entirely possible that tobacco was an important factor in the persistence of this lesion if it proved benign.

I am impressed by the statement that the pain was not relieved by a proper ulcer regimen even after several weeks in the hospital. This fact above all others suggests an infiltrating carcinoma. The gastric analysis in the hospital is of no help in clinical diagnosis.

I should like to know if an x-ray examination of the stomach was carried out at the clinic mentioned

in the record. If so, is it fair for me to have the information?

DR BENJAMIN CASTLEMAN If x-ray examination had been performed, I am sure that the results would have been incorporated in the abstract.

DR VOLWILER Do we have the x-ray films taken here?

DR RICHARD SCHATZKI The report given in the record may be misleading. Usually, the report in the officially prepared record is a statement of fact. Here a conclusion has been drawn. A large crater can be seen on the lesser curvature near the cardia of the stomach extending to the posterior wall. That is referred to in the report as a filling defect around the crater. The question is, Is it a tumor or inflammatory induration around a benign ulcer? Do you want me to give my own opinion? I do not know the case.

DR VOLWILER Why not give it when I have finished? How far below the entrance of the esophagus do you think this lesion is?

DR SCHATZKI I cannot see the actual cardia, but I should say that it was fairly close to it—within a few centimeters.

DR VOLWILER The inner contour of the crater is rather smooth?

DR SCHATZKI Yes.

DR VOLWILER This gastroscopic description leaves something to be desired. The site of an ulcer often cannot be visualized by the gastroscopist. But I should like to know whether peristalsis was active in the hyperemic area described and whether that particular portion of the gastric wall appeared rigid to air insufflation.

DR CASTLEMAN The only additional statement in the gastroscopist's report is that there was no evidence of infiltration.

DR VOLWILER I assume that that means that there was no obvious rigidity.

The Vincent Laboratory here has had a 20 per cent error in diagnosis from examination of fifty gastric-juice samples for malignant cells. An appreciable part of the error is believed to be due to the fact that the specimens are too old and are delivered more than an hour after being drawn from the patient. Better co-operation on our part may improve these statistics. Until the accuracy is considerably higher, this type of examination will not be useful clinically.

I assume that this man was operated on because of two facts that seriously raise the question of cancer: pain continued in spite of good management and was often not relieved by food or antacid, and x-ray study showed little reduction in the ulcer crater during the three weeks' hospital care.

DR SCHATZKI I did not realize that these films were taken on different dates. There is little change in the size of the ulcer, however.

DR VOLWILER Because of the anatomic location of the lesion, I believe that a transthoracic subtotal

gastrectomy was the operation performed. I believe that such an operation in a sixty-one-year-old man in this hospital carries at least a 10 to 15 per cent mortality risk. Is that a fair statement, Dr Welch?

DR CLAUDE E. WELCH It is too high, the mortality for subtotal transthoracic resections being 4 per cent. The percentage for total transthoracic resections for cancer is higher—around 30 per cent.

DR VOLWILER I had not realized that the percentage was so low. Therefore, one needs only to believe that the likelihood of cancer in this patient was greater than 4 per cent if that type of operation was considered to be a proper move. My choice between these two diagnoses can be little more than a guess. I believe, however, that the facts indicate that this was probably an infiltrating carcinoma.

DR CASTLEMAN What is your opinion, Dr Schatzki?

DR SCHATZKI Roentgenologically, the lesion appears to be benign. I cannot tell what the microscope will show.

DR CASTLEMAN The report of Dr Milford D. Schulz was as follows: "The findings are those of gastric ulcer, grossly benign."

DR WELCH I wonder if Dr Volwiler could explain the pain on the basis of the fact that the ulcer had perforated and therefore that carcinoma was not necessarily the cause. I do not argue about the treatment.

DR WALTER BAUER That was my thought, also.

DR VOLWILER That is a reasonable explanation.

CLINICAL DIAGNOSIS

Gastric ulcer, benign

DR VOLWILER'S DIAGNOSIS

Carcinoma of stomach

ANATOMICAL DIAGNOSIS

Benign peptic ulcer

PATHOLOGICAL DISCUSSION

DR CASTLEMAN This patient was operated on through the chest by Dr Carroll Miller. He did a subtotal gastrectomy and found, 4 cm. from the esophageal orifice on the lesser curvature, a large ulcer that had eroded into the pancreas. On gross examination the ulcer looked benign, although it was surrounded by a good deal of inflammatory reaction. Microscopically, sections confirmed the benign character of the lesion. It was an active ulcer, with a red-staining, fibrinoid base similar to that seen in active peptic ulcers.

DR VOLWILER Do we know anything about the incidence of recurrence of benign peptic ulcer with that sort of anastomosis? The top part of the stomach is removed, and the major acid-bearing portion and antrum are left in.

DR WELCH That is an interesting question, but we do not know anything about it yet. The antral mucosa remains, and there may be an increased tendency toward recurrence.

DR CASTLEMAN Still, you would not want to advise total gastrectomy at the first operation?

DR WELCH No.

DR SCHATZKI Have there been recurrences in cases in which that procedure has been done?

DR WELCH No recurrences have been observed to date, although the number of patients is small and the time interval short.

CASE 33272

PRESENTATION OF CASE

An eighteen-month-old boy entered the hospital because of edema of the face and lower extremities.

The child had been perfectly well until about three months before admission, when the first signs of an illness characterized by restlessness, irritability and a low-grade fever had developed. He slept and ate poorly and ran a continuous fever, the temperature never exceeding 101°F. After a few days, periorbital swelling appeared. The administration of tincture of digitalis for three days was sufficient to cause the edema to subside, but it recurred ten days after the drug had been withdrawn. Another course of digitalis was followed by a long remission during which the patient was kept inactive in bed. He occasionally refused a meal, but ate well at other times and did not appear ill. During this interval a heart murmur was heard for the first time. About three weeks before entry the child had suffered a brief attack of sore throat. Two weeks later he again appeared ill, with rapid panting respiration and slight cyanosis. On the day preceding admission edema of the lower extremities began to develop.

Birth had occurred at term after a normal gestation period. No complications accompanied the delivery or the neonatal period. The birth weight was 6 pounds, 11½ ounces. Mental and physical development proceeded normally until the present illness. The heart sounds were said to have been normal a year before the present illness. There were no siblings, and no familial diseases were reported.

Physical examination disclosed a child lying flat in bed and breathing rapidly at a rate of 36 per minute. The skin was dusky and cyanotic, the neck veins pulsated in the sitting position. Slight pitting edema extended over the ankles and lower portions of the legs. The chest was asymmetrical, bulging over the precordium. The heart was greatly enlarged to both the left and the right. The sounds had a pounding quality. The rhythm was regular. A loud, rather harsh systolic murmur audible all over the precordium radiated to the axilla and was heard posteriorly on both sides. A rolling mid-

diastolic murmur was heard best beneath the nipple and in the axilla. Both lung fields were clear. The liver edge extended 6 cm below the rib margin. No clubbing of the fingers was noted. Femoral pulsations were present. The patient weighed 20 pounds and was 30 inches tall.

The temperature was 98°F, the pulse 106, and the respirations 150. The blood pressure was 90 systolic, 60 diastolic.

Examination of the blood revealed a red-cell count of 4,650,000, with a hemoglobin of 10.9 gm, and a white-cell count of 19,200 that subsequently fell gradually to 8700. The urine gave a + to ++ test for albumin, and the sediment contained 0 to 4 red cells and 4 or 5 white cells per high-power field. In several 7-foot films of the chest, the heart shadow was greatly enlarged, the transverse diameter being 12.5 cm compared to an internal thoracic diameter of 15.5 cm., the contours were smoothly ovoid. No calcification was visible within the heart area. On fluoroscopy the pulsations were normal. The ribs were horizontal, and in addition, on the right side there was an anomaly of the fourth, fifth and sixth ribs. The lower-lung fields were almost completely obscured except at the bases laterally, where they were clear. The upper-lung fields were hazy. The pulmonary vascular markings were accentuated. No transposition of the great vessels could be detected. An electrocardiogram demonstrated sinoauricular tachycardia, and low T waves in Leads 1, 2 and 3, but the axis and PR interval were normal.

Treatment consisted of digitalis and restriction of fluids. A maintenance dose of 20 mg of digitalis daily sufficed to control the cardiac failure. By the tenth hospital day, the patient's general appearance was good. He was no longer dyspneic, and the edema had absorbed. Repetition of the chest films failed to demonstrate any marked change in the heart size. Another electrocardiogram recorded a drop in the rate to 100 per minute and a rise in the voltage of the T waves.

On the tenth day, mild coryza developed without fever. It lasted three days and then cleared spontaneously. A throat culture grew out a few colonies of Type 17 pneumococci, but subsequent ones were negative. Four blood samples were cultured in the course of a week. One was sterile in both flasks, nonhemolytic streptococci, *Staphylococcus aureus* and diphtheroids, respectively, were recovered from one flask in each of the other three cultures. The erythrocyte sedimentation rate (Westergren) at the end of the bout of coryza was 2 mm per hour, and on the twenty-fifth day it reached 16.5 mm per hour. The child was discharged home in the care of his physician on the twenty-sixth day.

About a year after discharge, the patient reported that the pulmonary murmur was fading without dyspnea, and that the clubbing of digitalis six d.

fingers had developed. The liver was palpable but nontender and not definitely enlarged. The heart remained extremely large.

At the age of three and a half years the patient weighed 31 pounds and was slightly over 38 inches tall. His condition was still fair, but a thrill had developed over the xiphoid process.

At the age of four he developed pneumonia, which cleared rapidly with penicillin, but from then on he had a bothersome cough and began to be decompensated. Edema first appeared in the extremities and then spread upward. Two months after the occurrence of the pneumonia, edema, ascites and dyspnea were severe. The patient died soon afterward.

DIFFERENTIAL DIAGNOSIS

DR RALPH A. ROSS: This case of recurrent cardiac decompensation started at the age of fifteen months and progressed, with remissions and recurrences, for nearly three years. The patient had been well up to the onset of the illness. He responded well to digitalis until the agonal period. The fact that physical development, which was said to have been normal for an eighteen-month-old infant, was at the lower limits for the age group may or may not be of significance. At the age of three and a half years the patient was well within the normal limits, so that if he was below par at admission to the hospital he made up for slow growth before he died.

On physical examination there were the classic signs of decompensation, — dyspnea, cyanosis, increased venous pressure, pulmonary congestion, hepatomegaly and edema, — as well as periorbital edema, which is unusual. The progressive signs of valvular damage are clear from the record, starting with a precordial systolic murmur before the first admission and then a definite mid-diastolic murmur over the mitral area, finally, a thrill developed before death.

The x-ray films showed general cardiac enlargement. May we see them? There were good pulsations on fluoroscopic examination, which seem to rule out a large collection of fluid.

DR TOUFIC KALIL: These are the rib anomalies. The heart is enlarged in all diameters, and the carina is widened behind the heart. The left main bronchus is raised considerably, which indicates some degree of enlargement of the left auricle, as well as of the ventricles.

DR ROSS: The electrocardiograms are not particularly helpful, indicating on the second tracing that some benefit, which could be determined from the clinical picture, had occurred. There was at no time any indication of polycythemia. There was a transient leukocytosis at the onset of the hospital stay. The urinary findings are probably explained best on the basis of cardiac decompensation. Certainly, the onset of periorbital edema, the acute decompensation, the enlargement of the heart and the

response to digitalis can be explained by myocarditis associated with glomerulonephritis, but the lack of further urinary findings and the subsequent course of the disease are against that diagnosis. There are other, more esoteric conditions that should be considered — von Gierke's disease, the glycogen-storage abnormality that occurs sometimes predominantly in the heart without much involvement of the rest of the body, clinically seems unlikely in a child who lived for four and a half years and grew relatively normally. We have no indication that there was any acetone in the urine or that the adrenalin test was done. I think that that diagnosis is unlikely. Interstitial myocarditis, described by Fiedler,¹ is a possibility if there is no other explanation for the enlarged heart. I simply bring it up as a thought. I do not know how we can go farther than that with it. Recently, at the Children's Hospital a case was diagnosed pathologically in a patient who had lived for a year without obvious cardiac symptoms, entered the hospital with what were thought to be pulmonary symptoms and died with a diagnosis of interstitial myocarditis as the only cause for the symptoms.

In favor of congenital heart disease is the presence of other anomalies, particularly those of the ribs. Congenital anomalies tend to be multiple. The bulging of the thorax noted three months after the onset of symptoms could have been due to acquired heart disease in a child of that age. How can we explain the progressive signs on the basis of congenital heart disease? The patient could have had bacterial endocarditis. The blood cultures in the hospital were negative. The long course after admission makes a diagnosis of subacute bacterial endocarditis untenable. An acute terminal bacterial endocarditis may, of course, have developed after the pneumonia. This leads me to the final possibility — acquired rheumatic heart disease. So far as rheumatic fever is concerned, no family history was noted, and the child was quite young, the disease, however, is occasionally seen at this age. The febrile episode before the onset of cardiac symptoms, the exacerbation two weeks after the respiratory infection, the failure of an exacerbation after pharyngitis apparently due to pneumococcus, the adequate growth of the child and the progressive development of murmurs seem to me to support the diagnosis of acquired rheumatic heart disease. Against this diagnosis is the response to digitalis. Usually, in children, cardiac decompensation associated with rheumatic heart disease is on the basis of acute infection, and digitalis rarely works so effectively as it apparently did in this case. The normal sedimentation rate can be disregarded because the child was probably in some degree of cardiac failure. Thus, I am left with the diagnosis of rheumatic heart disease and myocarditis, with mitral stenosis.

DR GERTRUD C. REYERSBACH: We were as puzzled as Dr. Ross, and he has mentioned the

points that made us doubt whether the child had rheumatic fever. We finally decided on rheumatic fever as a working diagnosis, but we were never quite convinced. The subsequent course does not bear it out. The child never had episodes of rheumatic fever according to what happened later. He developed a thrill over the xiphoid area, which is not consistent with mitral stenosis.

DR PAUL D WHITE I think that the murmurs observed in the hospital can be explained on the basis of enlargement of the heart alone without valvular disease necessarily. Frequently, during the early stages of rheumatic heart disease, perhaps in the first few years of a history of rheumatic fever, even mitral diastolic murmurs can be explained wholly by dilatation of the heart, without valvular deformity. Just what the thrill meant I do not know, but I do not recall that I found a thrill when I examined this patient at the time of admission. I should want to feel such a thrill before committing myself. It does look as if an infectious process were more probable than a congenital defect, because there had been fever and leukocytosis and no clear-cut characteristics of congenital anomalies — there was no clubbing of the fingers, for example. The cyanosis noted at first cleared up. It was not a constant cyanosis?

DR REYERSBACH No.

DR WHITE The electrocardiogram was normal, which is important from the standpoint of many congenital defects of the heart in which it would be abnormal. It could be normal in various infections, as for example acute rheumatic fever, despite the age, and that is to my mind the likeliest. Years ago I looked up the cardiac cases of infants, less than two years of age, with acute endocarditis at the Infants' Hospital in Boston, and as I recall there were a number of cases of bacterial infection but I do not remember finding any cases of rheumatic valvular involvement or rheumatic heart disease. Certainly, the diagnosis of pericarditis alone is not acceptable. Digitalis may help congestive failure in the presence of active rheumatic fever if the patient is treated at a favorable time — when the active infection has begun to subside.

CLINICAL DIAGNOSIS

Rheumatic heart disease, with mitral insufficiency

DR ROSS'S DIAGNOSES

Rheumatic fever

Rheumatic heart disease, with mitral involvement

ANATOMICAL DIAGNOSES

Healed endocarditis, type undetermined, of mitral and tricuspid valves and ventricular endocardium

Hypertrophy of heart

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY When a case is dubious on clinical grounds it often remains dubious on anatomic grounds. I was puzzled by this case too.

The flaps of the mitral valve were thickened and interadherent, and the chordae were shortened. There was a similar, although slighter, change in the tricuspid valve. The aortic and pulmonary valves were perfectly normal. Besides these valvular changes there were two unusual features. One was hypertrophy. The heart was four times the normal size for a child of this age. The hypertrophy was rather generalized in all chambers. There was also a marked degree of thickening in the ventricular endocardium. This appeared in patches in all four chambers and was almost diffuse in the left ventricle. We have a considerable number of sections from the heart, and microscopically they all show extreme thickening of the endocardium extending along the thebesian vessels into the myocardium but otherwise no trace of myocardial scarring, nowhere in the heart could we find anything that suggested an active rheumatic lesion. Sections of the valve showed simply a marked thickening of the connective tissue and some mucinous degeneration, but no inflammatory infiltration whatsoever, this does not suggest the picture of rheumatic endocarditis.

I am reminded of the case of another child that we had at these conferences a number of years ago, in which the clinical picture had been one of uncontrollable tachycardia of many months' duration. In that case the valves were negative, but there was the same thickening of the endocardium that this child showed. It was even more marked than in the case under discussion. It is rather flying in the face of Providence, when there is mitral stenosis and tricuspid involvement, to say that this was not rheumatic endocarditis, and yet I have genuine doubt that it was. If it was not rheumatic endocarditis, I do not know what it was.

DR WHITE Could bacterial endocarditis have produced this picture?

DR MALLORY I do not see how it could have. Endocardial fibrosis was marked and a characteristic feature of the whole process in the heart. I should not expect that with bacterial endocarditis, which is sharply limited to the leaflets or endocardium close to the valves. I should also not expect it to be spread diffusely on the ventricular endocardium.

DR WHITE Has Dr Bland any suggestions?

DR EDWARD F BLAND I have never seen anything like the patient that Dr Mallory has referred to, who died of a cerebral embolism. There was no embolus involved in the case under discussion. It does not sound like rheumatic heart disease clinically.

DR MALLORY. We have seen few children die of rheumatic heart disease in the absence of active rheumatic infection.

A SUBACUTE AND MALIGNANT FORM OF EPIDEMIC HEPATITIS

INFECTION hepatitis and homologous serum
jaundice are generally regarded as relatively mild dis-
eases that are associated with a low mortality rate—
about 0.2 per cent. Recovery is usually complete.
Cases do occur, however, in which these infections
are followed by a long-standing disability with a
variety of symptoms referable to the liver or nervous
system, or both.¹⁻³

Lucke⁴ described the pathological findings in the
livers of 14 cases observed in the Army after ap-
parent recovery from epidemic hepatitis. The livers
had become available for examination as a result of
fatal accidents or unrelated diseases from one to

fourteen months after the attack of hepatitis. From
the study of these livers, Lucke concluded that com-
plete restoration of the hepatic parenchyma usually
occurs in nonfatal cases of hepatitis. Regeneration
is usually complete provided that the destruction
is acute and the injury is not continued and provided
also that the destructive changes involve only the
hepatic cells and not the framework or vessels, all
this generally holds true in epidemic hepatitis.
Lucke could find no evidence of permanent damage
to the hepatic parenchyma.

Variants from the usual form of hepatitis have
been observed in the recent pandemic of hepatitis.
Attention has been called in these columns to the
fulminant type described by Lucke and Mallory,⁷ in
which death from acute hepatitis occurred within a
period of less than ten days after the onset of symp-
toms. In Denmark another malignant form of hep-
atitis has been observed in recent years. In the cases
that were observed there, death occurred several
months after the onset of acute hepatitis. Reports
of cases of this type are now available from hospitals
in Copenhagen. One by Jersild appears elsewhere
in this issue of the *Journal*, and another by Alsted⁸
has recently been published. The malignant
hepatitis observed in Denmark has occurred pre-
dominantly in women over forty-five years of age
and has a fatality rate of about 50 per cent. The
duration of illness is usually from four to nine
months, but both more acute and more protracted
cases have been observed. Clinically the cases are
characterized by jaundice, recurrent attacks of pain
associated with fever and evidence of portal obstruc-
tion—that is, edema and ascites. There is per-
sistent evidence of impaired liver function. The
pathological findings are largely limited to the liver,
in which there is widespread destruction of liver
tissue and, in the relatively chronic cases, replace-
ment by connective tissue.

The etiology of this form of hepatitis remains
obscure. On epidemiologic grounds it is believed
that this type has a different cause than that of the
usual cases of epidemic hepatitis and that it is dif-
ferent from homologous serum jaundice. Indeed, the
possibility is considered that it may not even be
an infectious disease, although no alternative causes
have been suggested. Similarly, no effective therapy

has been found other than the usual dietary and supportive regimes that are used in cases of hepatitis

The possibility that some special dietary or hormonal factors have altered the course of epidemic hepatitis in Denmark has been considered, but no evidence to support such a hypothesis has been offered. Interestingly enough, reports of similar cases from other European countries have not yet appeared, although it is possible that they have been encountered. Likewise, no such cases have as yet been recorded in large numbers in this country

DE SENECTUTE

THE lines "Gather ye rosebuds while ye may" and so forth, familiar to all of us, are still appropriate in these days of longer life but of accelerated living. They are, moreover, by one who knew his old age, Robert Herrick having put eighty-two summers behind him even in the seventeenth century, when the average span of man's life was well under forty years.

Not only has the duration of life nearly doubled since the over-ripe Herrick wrote his somewhat amorous lyrics, as a result, the average age of the populations of civilized countries has likewise steadily increased. The old, like the poor, will definitely be with us, and we must look to the better care of the aging, if they are to enjoy the fullness of their years. We must put more emphasis on the last of Shakespeare's seven periods of existence if we are to try and save the "lean and slipper'd pantaloons" from

second childishness, and mere oblivion,
Sans teeth, sans eyes, sans taste, sans everything

This interest in the problems of the old is fortunately quickening, here and abroad, to the point where geriatrics, caring for the tapering end of the

life line, has become as serious a specialty as has pediatrics for its beginning. It is wise to bear in mind that the sunset of man's life may have as vivid colors as its dawn, and he is much more conscious of it.

As Dr. Roger I. Lee* has pointed out, we have, by our care of the young, permitted many more people to become elderly without doing much to make that increase in years any happier or even more endurable. One of our tasks is to make these added years, for which most of us hope and which most of us dread, more pleasant ones to anticipate and to attain.

The declining years of life should have their own activities and their own compensations and their own type of oversight. They require certain dietary limitations, as of fats and roughage, and certain dietary reinforcements, as of vitamins and even digestants. Indeed, some of the proprietary firms are already promoting pap for the aged as well as pap for the young.

Age has its dignity, too often lost, let it also have its comfort, too often lacking. Let our second childhood at least share the consideration given our first. The enthusiastic lines of Rabbi Ben Ezra,

Grow old along with me!
The best is yet to be,
The last of life, for which the first is made,

particularly appropriate for a geriatric slogan, hold a promise that is still not always fulfilled but offers a target at which to shoot.

MASSACHUSETTS MEDICAL SOCIETY
A M A ANALYSIS OF POSTWAR
QUESTIONNAIRE

Discharged medical officers, according to an authorization from the American Medical Association, are entitled to one copy each of the "Analysis of the Postwar Questionnaire," which may be obtained from Frank G. Dickinson, Director, Bureau of Medical Economic Research, American Medical Association, 535 North Dearborn Street, Chicago 10.

This questionnaire was sent in November and December, 1946, to the 50,681 medical officers who were discharged prior to December 31, and sought opinions on the handling of medical matters during the war, with suggestions for improvement. Usable questionnaires returned totaled 26,018.

JOSEPH GARLAND, Secretary

BUREAU OF CLINICAL INFORMATION

All secretaries of various medical groups, such as special societies and alumni associations, are requested to notify the Bureau of Clinical Information regarding scheduled meetings, annual dinners and so forth. If such data are on file, it is hoped that duplication of dates can be avoided.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

DISTRIBUTION OF TOXIN-ANTITOXIN DISCONTINUED

The Public Health Council of the Commonwealth of Massachusetts voted on May 13 to discontinue the distribution of toxin-antitoxin mixture on June 30. This action is in accord with the recommendations of the National Institute of Health and of authorities on diphtheria immunization who have for some time past been unanimous in the opinion that toxin-antitoxin mixtures should be entirely replaced by diphtheria toxoid for diphtheria immunization.

For the information of those who have not before used diphtheria toxoid in immunizing adolescents and adults, the following points should be emphasized.

Recommendations

All children between six months and high school age should be immunized with diphtheria toxoid. The Schick test need not be performed on them before immunization since the majority of children of this age group are susceptible to diphtheria.

The Schick test should be performed on all persons of high-school age or over who are exposed to diphtheria or who are likely to come in contact with it. Interpretation of the test indicates subsequent procedure as follows:

- Schick positive, control negative, susceptible. Administer diphtheria toxoid with precautions as described below.
- Schick positive, control positive but smaller; immunity status uncertain. Such subjects are sensitive to the proteins of the diphtheria bacillus and may exhibit marked reactions to toxoid. Since they are few in number they may be re-Schicked two weeks later; this test being read at seven days. A negative test indicates that the subject possesses latent immunity awakened by the first test and therefore need not be immunized. If the test is positive, administer diphtheria toxoid with caution in small divided doses (see below).
- Schick and control show approximately equal reactions; immune but sensitive to diphtheria bacillus proteins ("pseudoreaction"). No immunization indicated.
- Schick negative, control negative; immune. No immunization indicated.

Dosage

For children three doses of 0.5, 1.0 and 1.0 cc. respectively given at intervals of three or four weeks, are advised. Fewer doses or administration at shorter intervals may fail to produce immunity. Injections should be made subcutaneously after preparing the skin at the site of injection with tincture of iodine and alcohol. Do not inject more than 1.0 cc. Discard remaining contents of used vials at end of clinic session.

The standard dosage schedule given above may cause moderate or occasional marked reactions in older children and adults. For this reason the first dose in such patients should be 0.1 cc. If no marked reaction follows, subsequent doses should be 0.5, 1.0 and 1.0 cc. respectively. If a marked reaction occurs, the dosage can be adjusted in accordance with the severity

of the reaction, and the interval between doses shortened provided a total of 2.5 cc. is administered.

Precautions

Local and even general reactions are exceptional in younger children, older children and adults are more liable to have severe local and general reactions so that toxoid should be given them only as described above. The reactions consist of varying degrees of redness, induration and swelling at the site of injection, sometimes accompanied by malaise, fever and headache which usually clear up within two days.

Duration of Immunity Reimmunization

Immunity of the level indicated by a negative Schick test develops in 90 to 95 per cent of children within three months after the administration of the last dose of diphtheria toxoid and may be expected to persist for at least several years. Follow up Schick tests six months after immunization will detect those who fail to respond to one immunizing course. Such persons should be given another series of inoculations.

It is recommended that children entering school who were immunized in infancy be given a stimulating dose of not over 0.5 cc. of toxoid. This is of particular importance in communities where the low incidence of diphtheria makes it advisable to compensate for the consequent lack of latent immunization.

COMMUNICABLE DISEASES IN MASSACHUSETTS FOR MAY, 1947

Résumé

Disease	May 1947	May 1946	Seven Year Median
Chancroid	0	1	1
Chicken pox	2594	2248	1276

Whooping cough	95	573	670

*Three-year median

†Five-year median

COMMENT

The diseases above the seven year median are chicken pox, diphtheria, Pfeiffer bacillus meningitis, salmonellosis and undulant fever.

Although below the prevalence for April diphtheria was still above the level in May 1946, and the seven year median. The decrease was probably largely due to the usual seasonal decline.

The increase in salmonellosis is not explained by an outbreak since more than one case was reported from only three communities and all those reported only two cases.

The diseases below the seven year median are bacillary dysentery, German measles, measles, meningococcal meningitis, mumps, poliomyelitis, scarlet fever and whooping cough.

This is the second consecutive month in which no cases of poliomyelitis were reported.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Diphtheria was reported from Boston 13, Brookline 1, Chelsea 10, Easthampton 2, Everett 1, Framingham 1, Hinsdale 1, Lynn 1, Manon 3, Medford 1, Revere 1, Somerville 1, Wakefield 1, Worcester 1, total, 38.

Dysentery amebic was reported from Lawrence 1, total 1.

Dysentery, bacillary, was reported from Worcester (State Hospital), 5, total, 5

Encephalitis, infectious, was reported from Taunton, 1, total, 1

Malaria was reported from Berkley, 1, Boston, 2, Haverhill, 1, Lynn, 1, Middleton, 1, Springfield, 1, Taunton, 1, Winchendon, 1, Worcester, 1, total, 10

Meningitis, meningococcal, was reported from Boston, 1, Fitchburg, 1, Lynn, 1, total, 3

Meningitis, Pfeiffer-bacillus, was reported from Boston, 2, Cambridge, 1, Chicopee, 1, Fitchburg, 1, Lowell, 1, Medford, 1, Northampton, 1, total, 8

Meningitis, pneumococcal, was reported from Cambridge, 1, total, 1

Meningitis, other forms, was reported from Boston, 2, Sudbury, 1, total, 3

Meningitis, undetermined, was reported from Brockton, 1, Cambridge, 1, Great Barrington, 1, Holbrook, 1, Northampton, 1, Springfield, 1, Wrentham, 1, total, 7

Salmonellosis was reported from Belmont, 1, Beverly, 1, Boston, 1, Grafton, 1, Lowell, 1, Quincy, 1, Revere, 1, Somerville, 2, Waltham, 2, Winchendon, 2, Worcester, 1, total, 14

Septic sore throat was reported from Boston, 7, Grafton, 1, Merrimac, 1, Taunton, 1, total, 10

Trichinosis was reported from Boston, 2, total, 2

Tularemia was reported from Springfield, 1, total, 1

Typhoid fever was reported from Quincy, 1, total, 1

Undulant fever was reported from Ashburnham, 1, Foxboro, 1, Ludlow, 1, Newton, 1, Paxton, 1, Weymouth, 1, Worcester, 2, total, 8

CONSULTATION CLINICS FOR CRIPPLED CHILDREN IN MASSACHUSETTS UNDER THE PROVISIONS OF THE SOCIAL SECURITY ACT

CLINIC	DATE	CLINIC CONSULTANT
Salem	July 7	Paul W. Hugenberger
Gardner (Worcester Subclinic)	July 8	John W. O'Meara
Pittsfield	July 9	Frank A. Slowick
Brockton	July 10	George W. Van Gorder
Worcester	July 18	John W. O'Meara
Hyannis	July 24	Paul L. Norton
Fall River	July 28	David S. Grice

Physicians referring new patients to clinics should get in touch with the district health officer to make appointments

REPORT OF MEETING

MASSACHUSETTS CENTRAL HEALTH COUNCIL

The annual meeting of the Massachusetts Central Health Council was held on May 1. The topic for discussion concerned local health councils, and the work of several of the more active local health councils was described.

Speaking for the Boston Health League, Miss Margaret Tracy stressed the importance for Boston of continuing the school-lunch program, as conducted in the Boston public schools by the director for school lunches, Miss Upham. The Health League has an active Committee on School Hygiene under the chairmanship of Dr. Charles H. Bradford. This committee is now studying problems relating to lunch-room services in the public schools of Boston. Another committee of the Boston Health League, under Mr. Horace Morison, is working on the question of reorientation of the work of the League in order that its usefulness may be increased.

The Health Committee of the Needham Community Council has been functioning for only one year, but Mrs. Francis K. Dermody was able to report that this committee has already been instrumental in the establishment of a much needed dental clinic.

Dr. Henry Godfrey, chairman of the Division of Hygiene of the Newton Community Council, reported that his committee has been successful in promoting x-ray examinations for tuberculosis among factory workers, has prepared health posters, is planning first-aid services for factories, is engaged

in cancer instruction for the public and is active in the field of nutrition.

Reporting for the Health Division of the Wellesley Community Council, Prof. Curtis M. Hilliard spoke of its service in an advisory capacity to men and women who have served in the armed forces, he also stressed its unique type of mental health program, and its co-operation with the Board of Health in the field of dental work and accident prevention. Each problem has been approached systematically. The first step is to study the matter, and the second to confer with all agencies involved and to formulate a program, the final step is to promote the program through interpretation to the public. Professor Hilliard summed up by saying: "It is hard to see, now that we have a community council how we could have gotten along without one."

Dr. James O. Walls, city health officer of Worcester, spoke for the four-year-old Health Division of the Worcester Community Council. Its groups cover the family and child, park and recreation, health, nutrition, crippled and handicapped and miscellaneous. The nutrition group brought the various nationalities together and secured better relations among them. The health division, by pushing, has doubled the budget for child guidance. The health group has done much to promote harmony and co-ordination of health programs in Worcester.

Mrs. Eleanor S. Washburn, director of the recently organized Massachusetts Community Organization Service, spoke briefly of its aims. She said that its purposes are to provide state-wide advisory services to communities concerning the basic requirements for sound, well rounded health, welfare, educational and recreational programs, to work for better co-ordination of the state-wide agencies, both public and privately supported, to promote local community planning co-ordinated with state planning, to give or secure technical assistance with community surveys and to provide an information service concerning social and health resources. Mrs. Washburn believes that her organization can assist the Central Health Council in its program of strengthening the organization of local health councils in many localities in which health councils have not yet been formed.

In opening the discussion, Dr. Elmer S. Bagnall, president of the Massachusetts Medical Society, stressed the great potential value of local health councils and expressed his interest in this phase of the program.

Mr. A. J. Strawson pointed out the importance of careful planning of the program in order that the interest of the participating may be fruitful and sustained.

Initial indifference and apathy, said Professor Hilliard, are inevitable, but they can be overcome by enthusiasm.

Dr. Hugh R. Leavell said that health councils should be organized on a voluntary basis and that adequate attention should be given to financing them.

At the business meeting of the Council the resignations of the president, Dr. George C. Shattuck, and of the vice-president, Dr. Channing Frothingham, were presented. The officers elected for the ensuing year were Dr. Hugh R. Leavell, president, Dr. David L. Belding, vice-president and Mr. Arthur J. Strawson, secretary-treasurer.

NOTICES

ANNOUNCEMENTS

Dr. Irving E. Goldberg, whose office is at 270 Commonwealth Avenue, Boston, announces that he has recently become a member of the Boston Anesthesia Service.

Dr. Sydney Grace announces the removal of his office from the practice of obstetrics and gynecology to 475 Commonwealth Avenue (Lister Building), Boston.

Dr. Otto Kant announces the opening of an office for the practice of neuropsychiatry at 19 Bay State Road, Boston. He is also retaining his Worcester office.

Dr. John C. Tate, who has returned from military service, announces the reopening of an office at 83 State Street, Springfield, for the practice of surgery.

TOTAL GASTRECTOMY

With Particular Reference to Closed (Aseptic) Esophagojejunostomy

REGINALD H. SMITHWICK, M.D.*

BOSTON

A DISCUSSION of carcinoma of the stomach should not fail to emphasize three points: the earliest symptoms of the disease are often mild and insidious and may consist of nothing more than indigestion, loss of appetite or easy fatigability; there is a great need for earlier diagnosis and operation if the survival rates are to be improved; and carcinoma of the stomach is responsible for more deaths per year than cancer of any other organ and for approximately 30 per cent of the total annual cancer mortality.

Many cases — 50 per cent in Ogilvie's¹ series — were obviously hopeless when first seen. Twenty per cent are found to be inoperable by pentoneoscopy or exploratory laparotomy. In a recent discussion of this problem Anglem² found 70 per cent of 188 cases to be inoperable for one reason or another. In a high percentage of resectable cases metastases have already occurred to the regional lymph nodes, thus significantly reducing the statistical chances for long survival or cure. In other cases direct extension of the growth to adjacent organs makes resection extremely difficult, inadvisable or impossible. In some cases the involvement of the stomach is so extensive that nothing less than a total gastrectomy can be considered.

This operation was first attempted by Conner³ in 1883. The first survival was reported by Schlatter⁴ in 1897. Since that time many articles have appeared in the literature. When Finney and Rienhoff⁵ discussed the matter in 1927, they were able to collect from the literature and their own 5 cases a total of 67 patients who had been subjected to total gastrectomy. The operative mortality approximated 50 per cent, in 58 per cent of cases the cause of death was peritonitis. In 1933 Roeder⁶ reported 3 cases, and so far as he could determine the total

number of gastrectomies recorded at that time was 88. The operative mortality was 50 per cent. He likewise emphasized the importance of peritonitis as a cause of death. In 1938 Allen⁷ reported 15 cases with 7 deaths — a mortality of 47 per cent. In their monograph on carcinoma of the stomach published in 1942, Walters, Gray and Priestley⁸ placed the operative mortality between 40 and 50 per cent and found peritonitis to be the cause of death in 55.6 per cent of cases. In 1944 Lahey and Marshall⁹ observed an operative mortality of 33 per cent, peritonitis being the cause of death in 58 per cent of fatal cases. These representative reports from the literature serve to emphasize two points: the over-all operative mortality following total gastrectomy has been high, and the principal cause of death has been peritonitis. In spite of this, a survey of the current literature reveals a notable reduction in operative mortality. In a series of 103 cases of total gastrectomy reported since 1942 and including the cases referred to below, there were only 15 operative deaths.¹⁰ 18-17

It is quite impossible to point to a single factor that is entirely responsible for this favorable trend. Better preoperative preparation and postoperative care are important. The advent of chemotherapy has without doubt exerted a favorable influence. Improvement in the technic of anesthesia — particularly in the administration of intratracheal ether and continuous spinal and procaine block — should also be mentioned. It has seemed to me, however, both from a survey of the literature and from my own few experiences, that the noteworthy reduction in operative mortality following total gastrectomy is due principally to improvements in surgical technic.

Many points about the technic of total gastrectomy have been emphasized. First of all are those related to an adequate operation for carcinoma, such as removal of regional lymph nodes and the great omentum. Other matters are stressed by

*Presented at the annual meeting of the New England Surgical Society, Worcester, October 5, 1946.

¹Professor of surgery, Boston University School of Medicine; surgeon-in-chief, Massachusetts Memorial Hospital; member, Board of Consultation, Massachusetts General Hospital.

some and not by others, such as mobilization of the left lobe of the liver, removal of the spleen and the question of whether the jejunal loop should be brought up in front of or behind the colon, whether some plastic procedure on the jejunal loops should be performed to make a substitute pouch for the stomach and whether some particular form of anesthesia should always be used. To my mind, these considerations are significant but not of primary importance. The need for an enterointerostomy has been insisted on by some and minimized by others, the majority appear to favor this method. Routine jejunostomy for postoperative

and Graham employ an additional layer of interrupted suture material between the esophagus and the jejunum prior to the placement of the inner continuous suture line. All emphasize the need for precaution against contamination by means of suction within the esophagus or externally and of careful walling off of the general peritoneal cavity. *It is at this particular point in the performance of total gastrectomy that most of the seeds of peritonitis are sown.* This may result in death solely from contamination at the time of operation. Fatal peritonitis may be due to subsequent separation and leakage from the anastomosis, which may be

TABLE 1 *Technic and Results of Total Gastrectomy in 10 Cases*

10	Graham	Closed (aseptic)	None	Patient living with recurrence 1 year and 1 month after operation

*This patient had a large ulcer situated on the greater curvature of the fundus of the stomach that was thought to be malignant but proved to be benign. All the other patients had carcinoma.

feeding, which has been suggested, may be regarded as optional — useful in some cases, but not essential in all. The incision of choice varies, but by and large, one placed to the left of the midline retracting the rectus muscle laterally and extending well up alongside the ensiform seems satisfactory. The costal cartilages can be divided if necessary. Care should be taken not to open the pleura. Of great value is the technic of esophagojejunal anastomosis. A major portion of the reduction in current operative mortality appears to be due to improvements in this particular step of the operation.

Many excellent articles have been written about total gastrectomy. Several authors — particularly Allen,^{7,18} Lahey,¹⁹ Lahey and Marshall^{9,20} and Graham²¹ — have stressed the technic of esophagojejunal anastomosis. Their articles have had a favorable effect on current operative mortality. There is one point in common — namely, the use of an outer layer of sutures between the jejunum and the diaphragm. This is generally a layer of interrupted, nonabsorbable suture material. Allen combines this with an inner continuous suture between the esophagus and the jejunum. Lahey

the result of impaired circulation, undue tension or delayed healing from contamination at the time of anastomosis.

My experiences are quite representative of those in the literature in general (Table 1). In brief, there were 2 operative deaths in 10 cases. In 3 cases an open anastomosis was performed. Both deaths occurred in this group and were due to peritonitis. End-to-side anastomoses were made between the esophagus and the jejunum, an outer layer of interrupted nonabsorbable suture material and an inner layer of continuous fine catgut being employed. The jejunum was not suspended to the diaphragm. One patient is alive and well ten and a half years after operation. In the second group of 7 cases, a similar suture technic was used. There were two variations, however, an outer layer of interrupted nonabsorbable suture material between the jejunum and the diaphragm was used according to the methods of Allen, Lahey or Graham. In addition, all anastomoses were of a closed or what might be called an "aseptic" variety. These were performed by a technic that has been found to be

safe and applicable to all other portions of the gastrointestinal tract.²³

My impression is that a closed technic of esophagojejunal anastomosis is a practical and useful adjunct to methods previously described in that it retains their most essential feature—namely, an outer suspensory suture line between the jejunum and the diaphragm—and at the same time further safeguards against the hazard of peritonitis due to contamination during open suture methods. There were no operative deaths and no evidence of peritonitis or wound infection in the 7 cases in which this procedure was employed. Its use in the various steps of total gastrectomy, including enteroenterostomy and closure of the duodenal stump, is illustrated in Figures 1, 2 and 3.

Of the 7 patients who survived total gastrectomy by the closed or aseptic technic, 2 are living and well three years and two months and five years and two months, respectively, following operation. The former was thought to have carcinoma both from the preoperative data and from the gross appearance at operation. Microscopically, however, the lesion proved to be a large, benign ulcer on the greater curvature of the fundus. In the latter case, the tumor was extensive, involving the pancreas and the transverse mesocolon. It was fixed and at first seemed inoperable. After a large portion of the transverse mesocolon, including a segment of the middle colic artery, had been resected, the spleen mobilized, and the tail and body of the pancreas resected immediately to the left of the superior mesenteric vessels, the lesion was found to be operable. It was not necessary to resect the transverse colon, the collateral circulation being adequate.

Thus, there were five-year survivals in 2 of the 9 cases of carcinoma, the second being that of the patient mentioned above who is living and well ten and a half years after operation. The lesions in both cases were large and palpable prior to operation and so extensive that nothing less than total excision could be performed. The regional lymph nodes were not involved. The preoperative and postoperative x-ray films and the microscopical characteristics of the tumors are shown in Figures 4, 5, 6 and 7.

Previous to 1946 the longest reported survival after total gastrectomy for carcinoma was that of Zikoff's²⁴ patient, who lived for four years and eight months after an operation performed in 1911. Recently, Lahey¹⁰ reported a patient living and well five years and four months after operation. He also recorded 2 patients living and well, respectively, seven years and one month following total gastrectomy for lymphosarcoma and eight years and seven months after total resection for leiomyosarcoma. These lesions are rare by comparison with carcinoma, and the long-range outlook is apparently better. At present, therefore, 3 patients who have lived for five years or more following total gastrec-

tomy for carcinoma are on record. The data are insufficient to permit the construction of survival curves following total gastrectomy, but some idea of the statistical chances of being alive from one

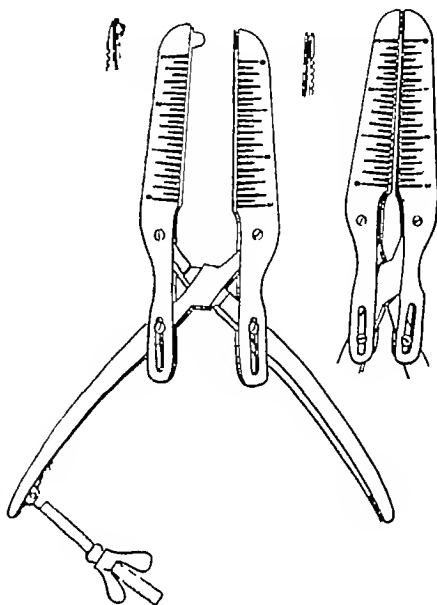

FIGURE 1

This thin-bladed clamp is placed on the end or side of the portion of intestine to be closed or anastomosed. The blades approximate in a parallel fashion, thus ensuring secure holding and equally distributed pressure on all portions of the segment included within it. A thumb-screw device permits controlled closure of the blades to the point of moderate crushing of the tissues. The width of the crushed tissue is about 1.5 mm. The bowel is divided distal to the clamp with a cautery, leaving a thin segment of tissue above the surface of the blade. This is cauterized slowly until it is black and well charred. This charred tissue is also about 1.5 mm. in thickness. A running suture is then placed in the charred tissue, constituting the first layer in the event that an end is to be turned in. If an anastomosis is to be performed, a basting suture is placed in the charred tissue instead. The grooves on the surface of the clamp are placed 3.0 mm. apart, and the running or basting suture is placed in these. The surface of the clamp is marked in inches to facilitate the selection of comparable portions of tissue for anastomosis. After either the running or basting suture is placed the clamp is removed. This technic provides complete hemostasis. The width of the turned-in tissue is narrow—about 3.0 mm. The turned-in tissue, which is completely denatured, separates in a few days. Anastomoses always open spontaneously when the basting sutures are withdrawn. There is no residual diaphragm to cause stenosis either immediately or later.

to ten years after operation is indicated in Table 2. Because of the marked reduction that has recently occurred in operative mortality following total gastrectomy, it seems proper to consider extending its use somewhat, particularly in cases involving

the body of the stomach in which a subtotal resection can be done but in which the margin of safety

ably have had total gastrectomies in the past had the mortality of the procedure not been prohibitive.

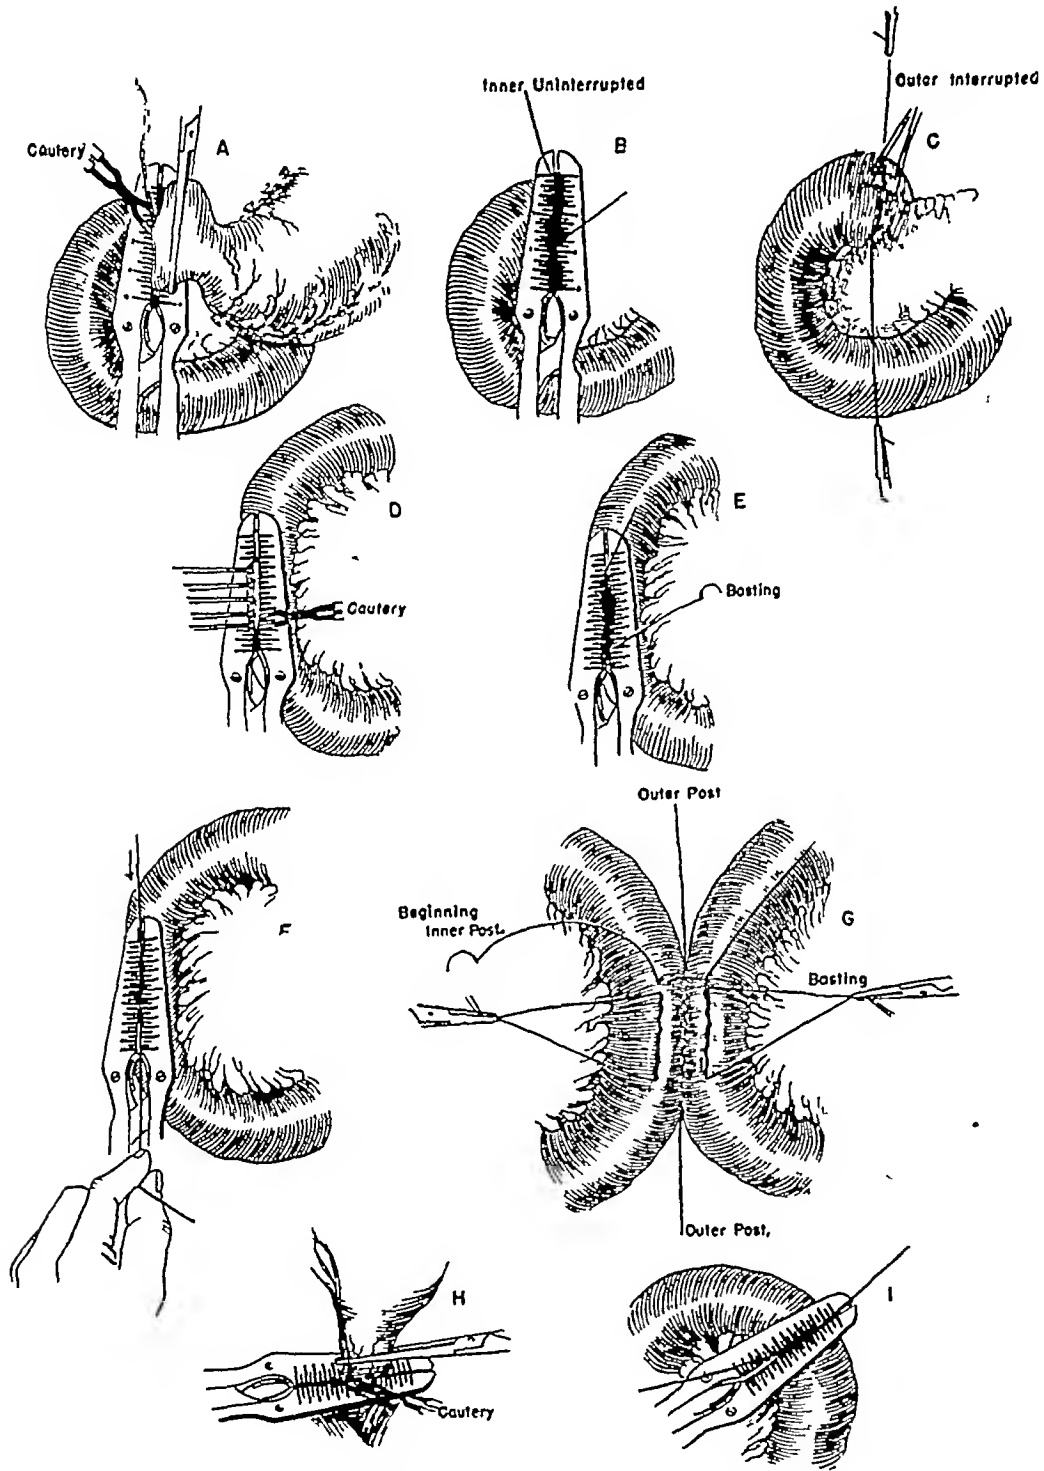

FIGURE 2

In the operation of total gastrectomy, it is necessary to turn in the duodenal stump (A, B, C) to perform an enteroenterostomy between the jejunal loops (D, E, F, G), and an end-to-side anastomosis between the esophagus and the jejunum (H, I). The use of this clamp in performing these various steps is illustrated. A running suture in the char, as well as a second serosal layer of sutures either interrupted or continuous, absorbable or nonabsorbable, the latter being covered by a tab of omentum, makes an adequate closure of the duodenal stump. An additional suture line in the serosa can be used if necessary. Two layers of fine continuous catgut are used in the performance of an enteroenterostomy.

made approximately two and a half months after the original operation. This was done by a trans-thoracic approach. There was no gross evidence of carcinoma in the specimen, which consisted of several centimeters of esophagus and jejunum. Malignant cells, however, were revealed by the microscope. About three weeks later, a further segment of duodenum was removed. Again, gross evidence of carcinoma was lacking, but the disease was apparent microscopically. The patient is now living a year and one month after the original operation, but is failing rapidly. There is a large neoplastic mass in the epigastrium, and he is having further difficulty in swallowing. A recent biopsy from the esophagus revealed evidence of carcinoma in the region of the anastomosis. This case serves to emphasize the need for removing a safe margin of normal tissue beyond the gross limits of the disease. If the lower end of the esophagus is known to be involved, a trans-thoracic approach should be used. Sweet²⁹ reported a series of total gastrectomies performed by this approach. In 2 cases the lower end of the esophagus was not involved. In 1 case a combined thoracoabdominal approach was used. There is no reason why the advantages of both the abdominal and the thoracic approaches cannot be utilized if necessary.

The remote effects of total gastrectomy on protein, carbohydrate, fat metabolism and intestinal motility and hematopoiesis are of interest. Few

dilates. In the course of years the loops become large. In Case 10, however, the patient began to experience difficulty in swallowing a few weeks after discharge. This progressed rapidly to the point of almost total obstruction in six additional weeks. This suggested the probability of residual cancer, since benign strictures following esophagojejunostomy usually do not progress so rapidly and are generally readily managed by dilatation. This patient did not respond to dilatation in the usual fashion, and a review of the specimen removed at operation revealed malignant cells extending to the limit of the resected esophagus. It also revealed that extension had occurred into the duodenal segment as well. There was no gross evidence of this at the time of operation. We thought we were well beyond the limits of the growth at both ends of the specimen. An x-ray film taken two weeks after operation showed a well functioning anastomosis and should be compared with a second taken four weeks later, which indicated almost total obstruction (Fig 8). The esophagojejunal anastomosis was resected, and a new anastomosis was

SUMMARY

The need for earlier diagnosis and earlier treatment of carcinoma of the stomach is emphasized. The frequency of this lesion and its importance as a cause of death are commented on.

A survey of the literature indicates a noteworthy recent decrease in operative mortality following total gastrectomy. Because of this, it seems proper to utilize this operation somewhat more frequently, particularly in cases in which a lesser procedure may jeopardize the chance for cure because of an inadequate margin of safety beyond the gross limits of disease.

Although the lower current operative mortality for total gastrectomy is undoubtedly due to a combination of factors, it is believed that improved surgical technique is one of the most important.

A closed (aseptic) method for esophagojejunostomy is described. This technique of anastomosis may further reduce the operative mortality by minimizing the hazard of peritonitis due to local contamination. The procedure has in other respects been as satisfactory as open methods of suture and has been found useful in all portions of the gastrointestinal tract.

Late complications, survival rates and remote effects of operation are commented on.

Two cases are reported in which the patients are living and well five years and two months and ten and a half years respectively following total gastrectomy for carcinoma. The latter appears to be the longest recorded survival following total gastrectomy for carcinoma.

DISCUSSION

DR. FRANK H. LAHEY (Boston): I think that we should all report our results with total gastrectomy because no one has dealt with this subject without being uncertain of the wisdom of the procedure. One of the early things that I said to our group is that when we have done enough total gastrectomies we must be sure that they are worth while, because so much of the stomach is involved in these cases of carcinoma, leiomyosarcoma or lymphosarcoma in which total gastrectomy is carried out that obviously the prospects of cure are slight.

We must then determine the prospects of prolongation of life and whether or not the operations are worth while. We have now done total gastrectomy in 92 cases over a period of years and Dr. Frances H. Smith, of the Clinic, has sent to *Surgery, Gynecology and Obstetrics* a good follow up study of 87 of these cases. As a result of this study it can be anticipated that 50 per cent of patients will survive for twelve months, 39 per cent for eighteen months, 30 per cent for twenty four months and 21 per cent for three years or more.

We have had a patient who had a total gastrectomy for leiomyosarcoma and who is alive and well nine years after operation, another, with lymphosarcoma, is alive and well seven years and eight months after operation. Still another is alive six years, and a fourth with carcinoma is alive and well six years after operation.

It is of interest to note the improvement in mortality. Our mortality for the entire series is 29 per cent. In the last 43 cases the mortality has been reduced to 16 per cent, and I do not believe that we have had a death in total gastrectomy in the last three years.

We no longer fear leakage. I think that our early mortality was largely the result of poor selection and selection, it seems to me is the consideration that must be urged on surgeons who are beginning their experience with total gastrectomy.

There are a number of things that one should do. I have published an article on operability with the abdomen open, in carcinoma of the stomach. We should be certain that there are not gravity metastases in the pelvis and particularly certain after direct inspection that there are not extensions in the root of the mesentery as demonstrated with the transverse colon turned up. One should be positive that there are not nodular chains running up the side of the esophagus through the diaphragm; these are often discovered only after the total gastrectomy is quite well along. Nothing I know of is so distressing as to have completed all the steps of a total gastrectomy except the anastomosis to the jejunum and to become aware of the fact that the lesion extends up beside the esophagus and is inoperable.

One of the things that should interest everyone is the blood picture after the operation. Dr. Smith has reviewed these cases and has found that 79 per cent of patients have red cell counts of 4,000,000 or higher. It is true that some of them must have assistance but it shows that they can maintain good blood pictures. Forty per cent had hemoglobin values of 13 gm.

In total gastrectomy there are any number of practical technical steps that we have learned from this experience. We have no fear of the open anastomoses. After the spleen has been removed, the left lobe of the liver has been mobilized and the vagi have been severed the esophagus can be pulled down a considerable distance and the anastomosis can be done relatively close to the abdominal wall.

For any of you who may do this operation, Dr. Marshall has devised what I think is one of the best steps toward making the operation easier — that is, the introduction of the posterior interrupted silk sutures, first leaving long loops with the esophagus turned up so that the interrupted sutures

are put in with long loops on the jejunum before the jejunum is opened. The jejunum is then opened well down in the field, and the loops must be pulled up and approximated. It is difficult to approximate the jejunum on the back of the esophagus unless it is done in this way. Total gastrectomy is technically feasible and is not too difficult an operation. Enteroenterostomy is desirable. In the last half of our cases all have had enteroenterostomies, because there is an irritating effect from the presence of bile regurgitating into the lower end of the esophagus, producing an esophagitis.

It is true that the linitis plastica type of carcinoma has a low grade of malignancy, because otherwise it is inconceivable that many of these patients in whom the entire stomach is replaced by carcinoma can have survived for a number of years. The linitis plastica type of carcinoma of the stomach must be a different lesion from the local carcinomas, which are often hopeless and recur quickly.

For that reason, I urge that everyone become familiar with this not too difficult operative procedure, particularly in the type of carcinoma that uses its energy in intramural infiltration rather than local ulceration and early metastatic involvement of neighboring structures.

DR CLAUDE C KELLY (Hartford, Connecticut) I have followed a patient for seven years after total gastrectomy. The patient has had a good deal of trouble in the last year. He did not report regularly for follow-up study. He was sent to a medical specialist, who found pernicious anemia. The patient was treated for that condition and is now working every day.

DR SMITHWICK (closing) Dr Kelly's seven-year cure following total gastrectomy for carcinoma is, of course, unusual, and his comments concerning the development of a primary type of anemia in this patient are of considerable interest, particularly the fact that the anemia has responded well to treatment.

The 3 patients in the series that I have reported today who are alive three, five and ten years after total gastrectomy

are at present being studied carefully from a metabolic point of view, with particular reference to the question of anemia.

Strangely enough there have been few reports of the primary type of anemia following total gastrectomy. Moynihan described a patient in detail who lived for three years and seven months following total gastrectomy for carcinoma and developed a severe anemia that was apparently fatal. Autopsy failed to reveal any evidence of carcinoma. The data, however, did not indicate with certainty the type of anemia. Most comments in the literature regarding anemia following total gastrectomy indicate that it has almost invariably been of a secondary variety. Most of these patients, however, were studied fairly soon after operation, and it is wholly possible that if more patients survive for longer periods there will be a higher incidence of primary anemia. In any event it apparently can be fairly readily managed by specific therapy so that it does not detract from an active and useful existence.

Other changes following total gastrectomy are of interest. There may be a disturbance in fat metabolism and a rather marked alteration in intestinal motility. There is considerable delay in the passage of barium from the jejunum to the large bowel, presumably owing to the lack of vagal innervation.

The marked reduction in operative mortality following total gastrectomy seems to make it proper to consider the use of this operation more frequently than in the past, particularly in patients with carcinoma of the body of the stomach that can be resected, leaving an inadequate margin of safety above the growth. I am certain that I, as well as many others, have avoided total gastrectomy in certain cases of this sort because of the high mortality. I believe that the time has come when one may properly be more radical under such circumstances.

THE EFFECT OF LARGE DOSAGES OF IRRADIATION ON GASTRIC ACIDITY

IRVING B. BRICK, M.D.*

BOSTON

IN PREVIOUS articles cases of gastric ulceration and the complications of hemorrhage and perforation incident to abdominal irradiation have been reported.^{1,2} In 6 cases, 4 of which are illustrated in Table 1, it was necessary to perform gastric resection. In these cases, as well as in many others of a similar type, treatment was given at the Radiation Therapy Section, Walter Reed General Hospital, for retroperitoneal metastatic disease or as a prophylaxis therefor in cases of testicular tumor. A 1,000,000-volt machine was used, and with the technics devised by Lieutenant Colonel Milton Friedman the dosage delivered to the stomach could be determined accurately. It was considered necessary to use a large x-ray dosage because of the radioresistance of some of these tumors and because of the metastatic involvement already present in some cases.

None of the patients had had previous gastrointestinal symptomatology or disease. Thus, coincidentally, the effects of irradiation on normal stomachs could be noted.

*Resident, Fifth and Sixth Medical Services (Boston University), Boston City Hospital, formerly, chief Gastrointestinal Section, Walter Reed General Hospital, Washington, D. C.

For some time since Bruegel³ reported the production of a temporary achlorhydria with radiation therapy, the use of x-ray therapy in peptic ulcer has held the attention of many workers. In studies on both human beings and animals, with great variations in technics and dosages, the consensus appears to be that there is a variable depression or suppression of gastric acidity. Palmer and Templeton,⁴ who present the most complete data, as well as a review of the previous work on this problem, are representatives of the school of thought that considers acid gastric juice to play an important role in the pathogenesis and healing of peptic ulcer. Achievement of neutralization or inhibition of acid secretion is therefore regarded as a highly desirable therapeutic goal. Before describing their results, the authors emphasize the potential dangers of radiation therapy, calling attention to reported cases of radiation injury to the small intestine and liver and also to the stomach in cases of carcinoma. No mention is made, however, of radiation injury to the normal stomach.

Palmer and Templeton treated 100 cases of peptic ulcer involving the stomach, duodenum and jejunum

with large dosages of radiation therapy, which they considered safe. A 200-kilovolt machine was used with 15-hy-15-cm portals anteriorly and posteriorly over the upper part of the stomach and with occasional positional check by fluoroscopy. Dosages varying from 1100 to 3600 r (measured in air) were employed. The authors concluded that there was definite gastric secretory depression, whose extent and duration were extremely variable and unre-

tors included 1000 kilovolts, 3 milliamperes, a filter of 3 mm tungsten and a focal skin distance of 70 or 100 cm, 88 to 40r, respectively, being delivered per minute. With the size of the portals used, 10 by 10 cm in most cases, the dosage of radiation was delivered to the antrum of the stomach, rather than to the upper part. In previous studies it was shown that the effects both radiographically and pathologically are confined mainly to the antral

dictable. A few toxic reactions were noted, including localized hepatic necrosis, diarrhea and anemia. No conclusions were drawn concerning the effect of radiation on peptic ulcer since the patients were given concurrent standard Sippy acid neutralization management. Histamine achlorhydria was observed after treatment in 35 of the 88 cases, the known duration of achlorhydria varying from a few days to a few months. The degree of depression of gastric acidity was not found to be related to initial acidity, sex, age, height, body weight, depth dose or dose of radiation. The high degree of individual variation is impressive. Palmer and Templeton soundly conclude that "the final effect of irradiation, not only on gastric secretion and the course of ulcer, but also on the normal tissue within the field of radiation, remains still to be determined."

MATERIAL AND METHOD

In the results presented below, there were marked differences in the clinical material from that of Palmer and Templeton. Our patients had normal stomachs and coincidentally received irradiation in the treatment of metastatic disease or in its prophylaxis. Unfortunately, values of gastric acidity were not obtained prior to radiation, and the data represent chronic, rather than acute, effects. The amount of irradiation given is in terms of tumor dose delivered at the level of the eleventh dorsal vertebra with a 1,000,000-volt machine. The physical fac-

and pyloric regions.^{1,2} Fractional gastric analysis with 0.5 cc. of histamine was performed in all cases.

RESULTS

Table 1 presents 4 cases in which partial gastric resection was performed because of the complications of gastric ulceration. The radiation doses were high, being over 6000 r in 2 cases and 4800 and 5096 r in the others. Perforation of the stomach was observed at operation in 3 cases, and yet the values of gastric acidity varied from low normal in 1 case to high in another, whereas the third was normal. Hemorrhage occurred in 2 cases, in 1 the values of gastric acidity were high, whereas in the other the values were low. The patient who received the smallest radiation dose (Case 3) had the most marked depression of gastric acidity. Fifty-seven days after completion of radiation, there was histamine achlorhydria. A hundred and sixty-five days later and one day prior to partial gastric resection, the values of acidity were still low, but at operation the patient had a large antral ulcer with subacute perforation and peritonitis. Certainly, the attainment of normal to low values of gastric acidity in this case was of no aid in preventing the serious complications of ulcer. Although the immediate effect on acidity of radiation in these cases was not obtained, it appears that no definite pattern of depression or stimulation is present after two months following completion of radiation.

Table 2 presents 5 cases in which the diagnosis of ulceration of the antral portion of the stomach was made by x-ray study or gastroscopy, or both. In these cases, at this writing, no complications have occurred, and the patients have improved symptomatically and by objective study. Again, there was no definite pattern of effect. In all the cases except

vertebra, was suspected of having caused radiation injury to the stomach. In all the other cases, the radiation dose was well above 4000 r. It might be argued that the ulcer was merely a coincidental occurrence, but the time of onset in relation to radiation therapy, the atypicality of symptoms, the antral location of the ulcer, the spasticity of the

one the dose was above 5000 r. The exception is worthy of detailed consideration.

CASE 9. A 31-year-old man had a seminoma of the left testicle removed on March 20, 1946. There was no history of gastrointestinal symptoms or disease. The patient received prophylactic radiation from April 17 to May 17, to the following levels: suprapubic, 2370 r, fourth lumbar, 2880 r, and eleventh dorsal, 2424 r. During treatment he had nausea for only 2 days. The patient felt well until 19 days after completion of radiation when he experienced pain in the epigastrium. The pain was described as a dull ache, with occasional periods of sharp burning lasting about 1 hour. There was no definite relation of the pain to meals, nor was relief afforded by food or soda. Attacks of pain lasting 1 hour were noted in the early morning. There was little nausea or vomiting and no hematemesis or melena. Vomiting was induced by the patient during an attack without relief.

Physical examination was negative except for pigmented brown areas over the radiation portals on the anterior abdomen. A gastrointestinal film on June 29 showed some spasticity of the antrum with a normal mucosal pattern. No organic lesion was noted in the esophagus, stomach or duodenum. Because of continuing symptoms, gastroscopy was performed on July 23, and an ulcer, 6 mm in diameter, was found on the greater curvature of the antrum just distal to the anterior end of the angulus. The ulcer was deep and clean, and its base was gray. There was no exudate or bleeding, and the margins of the ulcer showed no inflammatory reaction. A repeat x-ray film on July 27 showed an ulcer and a spastic antrum.

The patient was placed on a strict ulcer regime with alleviation of symptoms. At this writing, the patient has only occasional epigastric discomfort, which is of little consequence. Gastroscopy performed twice since the initial examination at intervals of 2 weeks showed slow healing of the ulcer.

Gastric analysis 59 days after radiation and during the height of the patient's symptoms was not remarkable.

This case is the first in which such small radiation dosage, 2424 r at the level of the eleventh dorsal

antrum noted by x-ray study and the gastroscopic appearance of the ulcer make it likely that radiation was responsible. As pointed out elsewhere the gastric changes due to radiation have been confined to the antrum and pylorus.² In the cases studied, there was marked individual variation in sensitivity to radiation dosage. There are on record cases in which doses similar to those given in Cases 1-4 caused no gastric symptomatology. Palmer and Templeton⁴ used radiation doses as high as 3600 r without development of ulceration, but in some cases, gastroscopically, superficial gastritis, variable in severity, was noted.

Several acidity studies were performed in Case 5, and it is noteworthy that the highest values of acidity were obtained in the second analysis at the height of the symptoms. A later gastric analysis showed marked reduction in the free acid values with concomitant symptomatic improvement. In Case 6, however, there was no such relation. At the time the first study was conducted, the patient was symptomatic, and the last two analyses were made during periods of marked improvement.

Table 3 lists 5 cases in which minimal or negative x-ray findings and symptomatic changes were present. The average radiation dose was 5000 r. The mean acidity values were, if anything, slightly higher than those in the other two groups. Again, there is no definite pattern of the acidity relative to dosage, length of time after radiation, symptoms and x-ray findings.

DISCUSSION

Although the material used in this report is not strictly analogous to that of Palmer and Templeton,⁴ the results are considered susceptible of comparison. With the larger dose used in our cases, the depression of acidity reported by Palmer and Templeton was not found, especially in the cases with prolonged follow-up studies. Since most of the values were obtained two months or more after com-

is regarded as having no place in the treatment of peptic ulcer. All workers in the field agree that in evaluating the results of any therapy in peptic ulcer, great caution must be exercised. The psychic effect of any kind of new therapy is well known. Thus, Sandweiss⁵ induced remissions of symptoms in a group of patients with peptic ulcer by intravenous injection of distilled water. In the cases of Palmer and Templeton, standard Sippy neutralization was used in addition to the radiation, and the authors

pletion of therapy, no statement regarding the immediate effect of radiation on acidity can be made. Certainly, the depression of acidity is short-lived, and the use of radiation to attain such a depression in cases of peptic ulcer, a chronic disease, therefore seems to have little place. If the effect of doses of radiation smaller than those used in this study depresses gastric acidity, it is difficult to understand why larger doses do not cause a greater depression. A possible explanation is that the radiation was directed to the antrum, whereas that in the cases of Palmer and Templeton was directed to the upper part of the stomach, the location of the major portion of the parietal cells. Palmer and Templeton also point out the extreme variability of the duration and extent of the depression of gastric secretion.

The patients in the series of Palmer and Templeton had proved peptic ulcers, whereas those in the cases discussed above were presumably free of gastrointestinal disease at the beginning of radiation therapy. Since radiation can cause definite injury to normal stomachs, it seems that an organ already the site of a disease of unknown etiology would be more susceptible to injury. No definite answer can be given to this problem, but in view of the variable effect on gastric acidity, the possibility of radiation injury to the stomach and the lack of correlation of acidity values to severity of symptoms and complications in peptic ulcer, radiation therapy

draw no conclusions concerning the efficacy of the radiation in the results obtained.

SUMMARY

Three groups of cases with varying degrees of radiation injury to the stomach are presented. No definite pattern of effect on gastric acidity was noted in these cases.

Depression of gastric acidity two months and longer after large doses of radiation was not found.

The marked variability of response of the normal stomach to radiation, varying from perforation and hemorrhage of ulcers to no changes clinically and by x-ray examination, with similar radiation dose, was also reflected in the marked variability of free hydrochloric acid values on gastric analysis.

The use of radiation has no place in the treatment of peptic ulcer, since it has been shown that deleterious effects on the stomach can be obtained with this agent. Since the individual response is variable, the result of radiation is difficult to predict.

CLINICAL NOTES

PARALYSIS OF THE ABDUCENS NERVE
FOLLOWING SPINAL ANESTHESIA*

REPORT OF A CASE

ANTHONY T. ROSE, M.D.,† AND

SAMUEL PRITZKER, M.D.‡

PHILADELPHIA

THE number of cases of paralysis of the abducens nerve following spinal anesthesia reported in the literature is surprisingly small, but the condition undoubtedly occurs more frequently than is generally supposed. Although it has been reported by Dattner and Thomas¹ following a simple lumbar puncture, most of the cases observed followed spinal anesthesia. In 1936 Woltman² reported 2 cases following inhalation anesthesia. Hayman and Wood³ presented 2 cases in 1942. Fairclough,⁴ in a review of 2021 cases of spinal anesthesia, found that paralysis of the sixth nerve had developed in 10 cases—an incidence of approximately 0.5 per cent. This seems rather high. In the past nine months at this hospital, spinal anesthesia was performed on 379 patients with only 1 case of abducens-nerve paralysis. Many of the cases were supplemented with diluted Pentothal solution administered by the continuous drip method.

The sixth nerve is involved in about 90 per cent of all cases of paralysis of the cranial nerves. Of the many theories regarding the pathogenesis, the most plausible, which are advanced by Hayman and Wood³ in their review of the etiologic factors, are mechanical, toxic and inflammatory. Adherents of the mechanical theory attach great importance to the alterations in blood and spinal-fluid pressures acting on a nerve that has a long, devious course and is in close proximity to bony structures. Fairclough,⁴ however, states that the trochlear (fourth) is the most slender cranial nerve and has the longest intracranial course. It is difficult to see how the etiology can be laid to the toxic or inflammatory factors, since cases have been reported following a simple diagnostic lumbar tap, when no foreign agent had been instilled in the subarachnoid space,

and since the spinal-fluid findings in the majority of cases are negative.

The onset of symptoms varies from three to twenty-one days. Both eyes are equally affected. Women are more prone to develop this complication than men. The syndrome seems to follow a definite pattern and is usually preceded by headache, dizziness, stiff neck, photophobia and diplopia.

The treatment is symptomatic. An eye patch may be worn to alleviate the diplopia. Recovery takes place spontaneously within a few weeks to a few months, usually with no residual paralysis. If the paralysis persists over two years, surgical correction may be undertaken.

CASE REPORT

A 37-year-old woman was admitted to the hospital on June 21, 1946, because of pain in the right upper abdomen of 2 years' duration. Physical examination was essentially negative. Roentgenograms showed biliary calculi, and a diagnosis of chronic cholelithiasis was made.

The patient was prepared for a cholecystectomy on July 8. Premedication consisted of 0.16 gm of morphine sulfate and 0.4 mg of atropine sulfate given subcutaneously 1 hour before operation. In the operating room the blood pressure was 130/80, and the pulse was 120. An injection of 120 mg of procaine diluted in 2 cc of spinal fluid was made between the second and third lumbar vertebrae, 20 mg of Methedrine was given intramuscularly 5 minutes before anesthesia was induced. Fifteen minutes after the spinal anesthesia the blood pressure had fallen to 90/60. The pulse was 80. An infusion of 1000 cc of 5 per cent glucose in physiologic saline solution was started. Thirty minutes after the onset of anesthesia the blood pressure was still 90/60. The patient was given 24 mg of ephedrine sulfate intravenously and 24 mg intramuscularly. Within 5 minutes the blood pressure had risen to 140/80, and the pulse to 100. The remainder of the course was not remarkable, and the patient was returned to bed in good condition.

Three days after operation the patient complained of severe headaches that lasted for 2 days. On the 6th postoperative day the patient still had slight headaches but also complained of double vision. At that time a convergent strabismus of the right eye was noted. The pupils were equal and slightly dilated, but reacted normally. Eye consultation confirmed the finding of paralysis of the right sixth cranial nerve. No treatment was advised.

The patient left the hospital on the 21st day after operation, when function of the right external rectus muscle was almost normal.

SUMMARY

A case of unilateral paralysis of the abducens nerve following spinal anesthesia is reported. Recovery was practically complete at the end of three weeks.

A COMPARISON OF THE VALUE OF THE RECTAL SWAB AND THE FECAL SPECIMEN IN CULTURING STOOLS*

WILLIAM J. H. FISCHER, JR., M.D.†

PROVINCENCE, RHODE ISLAND

THE widespread use by the armed forces in recent years of the rectal-swab technic for obtaining material for stool culture, described by Hardy, Watt and DeCapito,¹ has emphasized the value of this method in the study of large numbers of cases in epidemics of diarrheal disease and in the survey of food handlers. This technic is simple, easy to perform and readily adaptable for use in the home, office and hospital. Individual swabs in sterile test tubes assure immediate collection of material, aid in its prompt arrival at the laboratory and eliminate many of the cumbersome and unpleasant phases of the collection of the conventional fecal specimen. Whether or not the results of this method are comparable to those of an older, established procedure is important for complete evaluation of its efficiency. This study compares the results of stool cultures taken by the rectal swab and the conventional fecal specimen methods.

Rectal swab and fecal specimens taken on the same day were examined in 31 student nurses. Within two hours after collection the material obtained by these methods was inoculated onto eosin-methylene-blue agar and on Salmonella-Shigella agar (Difco). Two plates of each medium were used in all cases. After incubation at 37°C for twelve to twenty-four hours, the growth of coliform and colorless colonies was noted. The latter were inoculated into dif-

ferential mediums. Identification of the organisms was based on biochemical characteristics and, whenever possible, on serologic reactions.

Coliform colony growth resulted from inoculation by both methods in 29 of the 31 cases. There were no colonies on the plates from the swab in 1 case in which there was fair coliform growth from the fecal specimen. In another case no growth on any plates followed inoculation by both methods. In general coliform colonies were more abundant on the plates from the fecal specimen. No constant relation between the amount of material on the swab and the resulting colony growth was noted.

Nonlactose-fermenting organisms were isolated from the colorless colonies present in 6 of the 31 cases. In 2 of these cases the swab and the specimen showed almost identical results. *Proteus mirabilis* and a paracolon intermediate² were recovered by both methods in 1 case. In the other, *Pr. mirabilis* and *Pseudomonas aeruginosa* were present, *Pr. morgani* being isolated, in addition, from the fecal specimen. There were 3 cases in which colorless colonies appeared only on the plates inoculated with the rectal swabs. A paracolon intermediate was identified in two of these and a paracolon Aerobacter, a variant of Type 37711,³ was found in the other. The remaining case showed the presence of a paracolon Aerobacter, Type 32011,³ in the fecal specimen.

* * *

Under the conditions of this study, the rectal-swab method and the conventional fecal-specimen method appear to be of comparable value in culturing stools.

MEDICAL PROGRESS

GYNECOLOGY: THE VAGINAL SMEAR

HOWARD ULFELDER, M D,* AND JOE V. MEIGS, M D†

BOSTON

THE mammalian female genital tract is lined throughout with epithelium that grows and recedes in response to alterations in the concentration of ovarian hormone¹ In the vagina, cyclic changes are described that include variations in the activity of the basal layer, in the thickness of the epithelium and in the maturity (cornification) of the squamous cells at the surface^{2,3} Like epithelium elsewhere, the vagina undergoes continuous desquamation A random sample of the fluid present at a given time contains cells recently shed from various parts of the genital canal, together with leukocytes, erythrocytes, bacteria and mucus

Stockard and Papanicolaou⁴ made a careful study of the vaginal cytology in the guinea pig and correlated it with anatomic and histologic findings in the uterus and ovaries They concluded that four stages of the sexual cycle and the time of ovulation could be detected with accuracy through the medium of the vaginal smear Identical observations have been made in rats and mice

Although similar changes were observed in monkeys,¹ there was less marked cyclic variation than in rodents The vaginal smear could not be used as a dependable index of the date of ovulation, or even to tell whether ovulation had taken place⁵ This difference between rodents and higher forms is apparently closely related to the disappearance in the latter of a specific short period of estrus with the extreme degree of vaginal cornification seen, for example, in the rat

TECHNIC

Material for examination may be obtained directly from the vagina or from the blade of a bivalve speculum if no lubricant has been used The secretion is transferred to a glass slide by means of a cotton swab, wire loop or pipette Many use the simple method described by Papanicolaou² of direct vaginal aspiration with a rubber suction bulb attached to a length of dry glass tubing Effective suction can be exerted if the tip of the pipette has been flamed down to a lumen of capillary size. Material is expelled on a glass slide, spread thin with the tip of the pipette, and placed at once in a fixative solution of equal parts of 95 per cent ethyl alcohol and ether Various stains have been devised A trichrome stain⁶ has been most effective

in bringing out nuclear detail Details of preparation and staining are completely described in several publications^{2,6,7}

INTERPRETATION BASED ON VARIATIONS IN THE RELATIVE NUMBER OF NORMAL CONSTITUENTS

Papanicolaou² reported the first careful studies on the vaginal smear in human beings He described definite cyclic variation in both epithelial and blood constituents and traced analogies with the cycle in rodents After menstruation he observed a steady increase of cornified epithelial cells with a decrease in leukocytes and a "clean" appearance to the smear With ovulation there is a tendency for the epithelial cells to curl and clump and for leukocytes to reappear in large numbers A few erythrocytes are often noted at this time Between ovulation and menstruation, changes in the vaginal cytology are less constant With menstruation, of course, the outstanding finding is the presence of erythrocytes in great numbers Definite alterations in pregnancy are also described — chiefly, an increase in the size of the cells and the appearance of large flat cells Some correlation with ovarian histology was possible in 17 patients who came to operation during the course of the investigation

Heller and his co-workers⁸ were able to examine the uterus and ovaries in 28 women who had been studied by means of vaginal smears before and after operation They found the smear an unreliable index of the state of the ovaries A critical review of various reports^{2,5,8,9} justifies the conclusions of Neustaedter and Mackenzie¹⁰ that for practical purposes the vaginal smear usually yields correct information only regarding estrogen elaboration during the proliferative phase of the cycle The smear is difficult to evaluate during the progestational phase and gives no definite indication of corpus luteum action and therefore no clue concerning whether or not ovulation has taken place Rakoff¹¹ is substantially in agreement, although he says that "the experienced observer often can note changes in the day-to-day smears suggestive of corpus luteum function as well"

Reports on the use of the vaginal smear in abnormal menstrual states are rare Shorr and Papanicolaou¹² suggest a reclassification of the amenorrheas into three groups one showing repeatedly the atrophic smears of ovarian inactivity, another demonstrating continuous low-grade estrin effect

*Assistant surgeon, Massachusetts General Hospital

†Clinical professor of gynecology, Harvard Medical School, chief Gynecological Service (Vincent Memorial Hospital), Massachusetts General Hospital

and still another exhibiting cyclic variations without overt menstruation. They cite a case treated with gonadotropic hormone with conversion of the smear to the follicular type and menstruation. There was nothing to suggest that ovulation had occurred, however. Using women with well established menopause, both clinically and by smear, Short¹² studied the effect of androgen and progesterone on the vaginal cytology. The male sex hormone failed to alter an atrophic smear, although it reduced the urinary prolan excretion to normal levels. Moreover, it caused reversion of the estrogen-induced proliferative smear to the atrophic type, even with continuation of estrogen therapy. Progesterone given with estrogen produced changes in the smear comparable to the postovulatory phase of the menstrual cycle. Most workers, however, have found it impossible to evaluate or control progesterone therapy by means of smears, and Mack⁷ in a comprehensive review concludes that only degrees of estrogen effect can readily be distinguished by the smear technic.

It is obvious that the menopausal state is the one most easily detected in the vaginal smear. Characteristically, there is almost complete disappearance of superficial cornified cells.¹⁵ Cells from deeper and basal layers are much in evidence, together with many leukocytes. The administration of estrogenic drugs in the majority of patients converts an atrophic smear into one showing full cornification. Unfortunately, some degree of estrogenic effect is apparent in the smears of many patients with well established clinical menopause. No consistent correlation between the appearance of the smear and the urinary excretion of gonadotropic hormone is manifest¹ or with symptoms either before or after therapy.^{5, 16} Although the smear cannot be used as a delicate control for estrogen therapy, it will reveal whether, in a patient with symptoms suggestive of the climacteric, there is concomitant vaginal atrophy and whether, after treatment of a patient with estrogen fails to obtain relief of symptoms, a physiologic effect has been produced—that is, whether medication has been taken as directed and is being utilized (metabolized) in a normal fashion.

The response of the atrophic vaginal mucosa to estrogen readily suggests itself as a simple method of hormone assay in every way comparable to that used in animals.⁷ Both the study of cytologic detail and the less painstaking glycogen index have been applied in this connection. The method is reliable in determining comparable potencies of various estrogens by successive trial in the same woman, but the amount of any one estrogen needed to produce the same vaginal changes in other castrate women shows marked variation.¹⁸ Similar results are reported in experiments on the antiestrogenic effect of androgens.¹⁹

INTERPRETATION BASED ON THE PRESENCE OF ABNORMAL CONSTITUENTS

While observing and classifying the cell types found in human vaginal smears, Papanicolaou¹⁷ occasionally noted conspicuous cells that failed to conform to any previous characterization. These were in patients with cancer of the genital tract. After the accumulation of a large body of evidence, a solid foundation was laid for the cytologic method of cancer diagnosis.¹⁸ Facility in the detection of abnormal cells depends, of course, on complete familiarity with normal cytology.

Criteria of abnormality are a variation in nuclear size and staining properties and an increase in nucleus relative to the cytoplasm.^{18, 19} The cells tend to occur in clumps, and individual outlines are often indistinguishable. Leukocytes are abundant. Malignant giant cells are described, and must be distinguished from benign multinucleated cells. In the more differentiated lesions unusual forms, such as "tadpole" and "fiber" cells, may be encountered. Comparison between the vaginal smear, a smear taken directly from the tumor and the pathological section of the tumor¹⁸ shows a morphologic resemblance between the cells that is strong presumptive evidence of a common origin.

Errors associated with the method are of two types: cancer in the presence of a negative smear and cases in which the smear is positive but no cancer can be found. The first error is inherent in the method, since no tumor cells can be seen if none are present on the slide. Papanicolaou and Marchetti²⁰ suggest taking smears directly from the cervical canal and endometrium to reduce the likelihood of this mistake. Final judgment regarding errors of the second type must await a series studied by serial section of all available operative and post-mortem material. Biopsy, curettage and even routine pathological examination, as Mallory²¹ points out, may miss small lesions. A review of reported series reveals that about 6 per cent of patients with cancer of the cervix have negative smears, whereas cancer of the endometrium is missed in about 15 per cent of cases.^{18, 22-24} Of patients in whom cancer cannot be found, between 1 and 2 per cent have what are reported to be positive smears.

Increasing interest in the technic has been stimulated by two facts. In the first place the universal applicability and the ease and rapidity with which the smear can be taken make it ideal for screening large groups of persons. Secondly, every published report includes protocols of patients in whom positive smears called attention to cancer before it had given the slightest hint of its existence. Even carcinoma *in situ* has been detected in this fashion.^{22, 23, 24} It should be noted that the method is finding ready application in the diagnosis of cancer of the bronchus, stomach and urinary tract.¹⁸

Graham²⁷ recently described and discussed the significance of changes observed in the vaginal cytology of women receiving radiation therapy for carcinoma of the cervix. Characteristic increase in cell size, vacuolization and abnormal nuclear growth and degeneration were seen in the normal as well as the malignant constituents. In a group of patients showing good radiation response by Graham's criteria, the short-term results of therapy were strikingly better than those in a similar group that had shown a poor response to radiation. This observation offers promise of a new and exceedingly valuable application of the vaginal smear. A variety of radiologic attacks on the disease can be assessed without the need of three-year or five-year clinical results. Moreover, heroic surgery may eradicate occasional moderately advanced cervical cancers, if a method of selecting cases with a poor prognosis under radiation treatment is devised.

A final use for the smear should be mentioned. In the cancer follow-up clinic it affords a simple check on the clinical impression regarding local recurrence of disease. This is particularly important in cases in which extensive adhesions and atresia make adequate examination impossible. Approximately 13 per cent of a series reported by Meigs et al.²² fall into this category, and among their cases is one of a patient in whom, after radiation for cancer of the cervix, positive smears were found consistently for seven months before biopsy confirmation could be obtained.

CONCLUSIONS

The vaginal smear is a simple, painless and universally applicable method of observing and recording certain changes in the status of the female internal genitalia.

Degrees of estrogenic effect can be distinguished in the vaginal smear.

By means of day-to-day smears, an experienced observer can also occasionally draw conclusions regarding corpus-luteum function.

In cancer of the genital tract, the smear is of help not only in diagnosis but also in prognosis and in the detection of persistent or recurrent disease.

CASE 33281

PRESENTATION OF CASE

A twenty-six-year-old draftsman was admitted to the hospital complaining of recurrent attacks of painful swelling of the joints.

At the age of fourteen attacks of swelling and pain in the joints developed. They first involved one ankle and subsided spontaneously after a few weeks, without residua. Later during the same year, however, the knees became swollen and stiff. The patient was thought to have rheumatic fever and was put to bed for nine months. During that time he had several recurrences but was finally allowed to return to school after a short period of freedom from symptoms. Thereafter, he was never free from attacks for long. The swelling and pain later involved the knees, ankles, hips, wrists, elbows, shoulders and fingers. There was never any known precipitating cause. The joints became swollen, painful and stiff, improving symptomatically with aspirin therapy. In the early stages of the illness no permanent changes of the joints were noted. The patient was able to complete high school but absence from classes necessitated by the illness forced him to leave college. Six years before admission he was studied in New York City for three months and given a course of each of the new sulfonamides without effect. The knee was tapped at that time, and a pleomorphic streptobacillus was isolated. From this organism a vaccine was made and injected, also without effect. Many attacks continued each year, with minimal aches and pains between major flare-ups. Four years before admission the patient noticed stiffness and limitation of motion of the right hip that did not subside after an attack. He moved to the Southwest for a change in climate, but the course continued unchanged, with periodic attacks. He returned to New York City, where several acute episodes were treated with courses of gold and Ertron without noticeable benefit or toxic effect. During the year before entry he felt well, having about ten months with no symptoms other than the stiffness of the right hip. About four months before admission a recurrence worse

than any previous attacks occurred, with marked swelling of the right knee and less severe involvement of all the other joints. Six weeks later he was seen for the first time in the Out Patient Department, where he showed some residual involvement of both knees and the left temporomandibular joints, as well as a 15° permanent flexion of the right knee with marked limitation of motion. Three weeks later the right knee was tapped, and 50 cc. of cloudy yellow fluid was withdrawn, analysis of which showed 5750 white cells per cubic millimeter with 66 per cent neutrophils, 18 per cent lymphocytes and 16 per cent monocytes, the sugar level was 132 mg per 100 cc (serum, 125 mg per 100 cc), cultures, including one for pleuropneumonia-like organisms, were negative. Examination of the urine showed a +++ test for albumin. No enlargement of the thyroid gland was noted at that time. The knee swelling gradually subsided while the patient remained at home in bed. Three weeks before admission he had an attack of "grippe" with fever, the temperature ranging up to 104°F, and with cough and malaise. There was no chill or sore throat. He was seen by a physician, who noted that the thyroid gland was five times its normal size. The patient had not noticed this obvious swelling of the neck, since it had caused no pain and he had worn no collar while bedridden for the previous ten weeks. His fiancée believed that it had been present before the onset of the febrile illness. There was no tenderness over the thyroid gland and no symptoms of pressure or constriction. The temperature gradually came down with treatment by oral penicillin. There was a loss of appetite and perhaps some weight loss, but the amount was not known. The patient had been under emotional tension owing to the flare-up of the disease, loss of his job and so forth, but he had had no excess of sweating, tremor, diarrhea, intolerance to heat or increase in the prominence of the eyes. No history suggestive of an intake of goitrogenic substance could be elicited. At the time of admission the patient considered the thyroid gland to be somewhat smaller than it had been when the enlargement was first noted.

There was no family history of arthritis or thyroid disease.

Physical examination revealed a well developed man in no distress. The skin was somewhat pale but not excessively moist. No superficial lymph nodes were palpable. The eyes were prominent, with no lid or globe lag. The thyroid gland was diffusely enlarged six to eight times the normal size, the right lobe being larger than the left. Several examiners were able to feel the pyramidal lobe. The gland was firm but not hard and slightly irregular in outline without fixation, tenderness or bruit. The musculature of the arms and legs showed considerable atrophy. No swelling, tenderness or limita-

tion of motion of any joints other than that of the right hip was noted. The fingers showed a spindle deformity. Examination of the heart, lungs and abdomen was negative.

The temperature was 97.2°F, the pulse 85, and the respirations 17.

Examination of the blood disclosed a red-cell count of 5,100,000 and a white-cell count of 14,000, with 71 per cent neutrophils, 23 per cent lymphocytes, 4 per cent monocytes and 1 per cent eosinophils and basophils. The hematocrit was 38 per cent, and the sedimentation rate 122 mm per minute. On several analyses the urine gave ++ and +++ tests for albumin, with specific gravities from 1.008 to 1.020 and no sugar, and the sediment contained occasional hyaline and granular casts, 3 to 6 red cells and 5 to 10 white cells per high-power field. The nonprotein nitrogen was 16 mg, the cholesterol 263 mg, and the total protein 6.3 gm per 100 cc, the protein-bound iodine being 5.0 microgm per 100 cc. A Congo-red test showed 51 per cent retention. The basal metabolic rates were -9 and -10 per cent. A radioactive-iodine-excretion test was normal, with 69 per cent excretion within forty-eight hours.

X-ray examination of the chest was negative, and intravenous pyelograms were normal.

In the hospital the patient's condition remained unchanged. A biopsy of the thyroid gland was taken on the twenty-first hospital day.

DIFFERENTIAL DIAGNOSIS

DR ALFRED KRANES The last statement indicates that the diagnosis was probably made from the biopsy of the thyroid gland, although we have no assurance that that was so. Possibly, something was found that led to subsequent treatment or operation about which we are not told. But since this patient was in fairly good condition on admission, I suppose that he survived the biopsy and therefore assume that the diagnosis is to be narrowed down essentially to the lesion of the thyroid gland.

May we see the x-ray films? Although examination is reported to have been negative, there are one or two things that I think should be brought out. I am particularly interested in knowing whether any enlarged mediastinal lymph nodes were demonstrated—I am keeping in mind the possibility of thyroid lymphoma.

DR STANLEY M. WYMAN The films of the chest show the lung fields to be clear. The heart shadow is not remarkable. There are no visibly enlarged mediastinal or hilar nodes. The plain film of the abdomen shows the liver edge to be within normal limits. The spleen may be wider than usual.

DR KRANES Do you think that the spleen is enlarged?

DR WYMAN Possibly so, but there is no good x-ray evidence. It is wider than usual, but not definitely enlarged.

There is scoliosis of the lumbar spine to the right. The kidneys are not remarkable. There are definite arthritic changes about both hip joints, with narrowing of the joint spaces. There is some pseudocyst formation. The sacroiliac joints are also somewhat cloudy. The renal function is good, with satisfactory excretion of the dye. The calyces, pelves and ureters are not remarkable. The bladder shadow is not visualized.

DR KRANES I was interested in two things: whether there was any enlargement of the mediastinal lymph nodes and, in view of the albuminuria and hematuria, how well the intravenous dye was excreted.

I cannot explain why the thyroid gland increased so rapidly in size. Possibly, it did not grow so fast as the record indicated. Perhaps the failure to note it at the time of the examination in the Out Patient Department was due to the facts that at that time more interest was concentrated on the joints and that the thyroid gland was not carefully examined. A thyroid gland five or six times the normal size, however, should be reasonably apparent. Nonetheless, it is slightly difficult for me to believe that the gland increased so rapidly—actually within two months. It would be of some interest to know whether the physician who noticed the original enlargement was the one who had seen the patient right along. If so, this observation would carry more weight. It is interesting that the patient himself was not aware of the considerable enlargement of the thyroid gland—a phenomenon that we often run into.

What diseases of the thyroid gland will lead to rapid enlargement? The most frequent, of course, is Graves's disease, in which the goiter may appear quite rapidly, although it usually does not. Certainly, this history does not suggest Graves's disease. All the evidence we have indicates that the goiter was nontoxic. The physical examination and the laboratory evidence are against Graves's disease, which must therefore be excluded.

Another cause of rapid enlargement of the thyroid gland is acute inflammation. I wondered whether the acute febrile episode during which the gland was first noted was due to acute thyroiditis. If it was, I do not see how it is possible to make such a diagnosis in the absence of all the signs that usually accompany that condition—pain, tenderness and heat. There was swelling, to be sure, but none of the other evidences of inflammation, and without them I cannot seriously entertain the diagnosis of acute thyroiditis, although that would explain the rapid enlargement of the gland.

Another possibility to be considered is malignant tumor, although the description of the gland certainly does not suggest it. Carcinoma, I think, is extremely unlikely because of the patient's age and the fact that the thyroid gland was diffusely enlarged. I should think that a malignant thyroid

gland of this size would have been more adherent to surrounding structures, as well as irregular and nodular. The same objections, however, do not hold for lymphoma. I do not see how one can exclude lymphoma of the thyroid gland except that there is no evidence of it anywhere else in the body. And to make that diagnosis without any confirmatory evidence is rather hazardous.

The most frequent cause of gradual enlargement is the ordinary colloid goiter. But there are a number of objections to that. If this had been colloid goiter one would expect the enlargement to have been present for many years. More important than anything else, I find it hard to believe that I should have been asked to discuss a colloid goiter at a clinicopathological conference. It is such an extremely commonplace condition with so little clinical or pathological interest that I exclude it for that reason more than for any other.

Against chronic thyroiditis is the description of the gland, which does not fit with either the Riedel or the Hashimoto type of chronic thyroiditis. Such glands are usually extremely hard, often described as ligneous, and usually adherent to surrounding and underlying tissue, frequently causing pressure symptoms. The Hashimoto type is extremely rare and is practically excluded in this case, because of the sex, being almost exclusively confined to women. Since the gland in the case under discussion was firm but not really hard and not adherent to the other structures the diagnosis of chronic thyroiditis is quite unlikely.

Let us for a moment pass on to a discussion of the arthritis to see if we can obtain a clue there. I assume that it was rheumatoid arthritis. Certainly, the therapy prescribed over many years leads one to that belief. It is unusual, however, to see so little joint involvement in a patient who has had severe rheumatoid arthritis for twelve years—I should have expected a great deal more. Ordinarily, one does not think of rheumatoid arthritis as being a cause of enlargement of the thyroid gland, but we might search around for certain complications of rheumatoid arthritis, the most frequent of which is amyloid disease. I am rather inclined to believe that the patient did have amyloid disease, chiefly because of the presence of albuminuria and of slight hypercholesterolemia and probably also because of the Congo-red test—I might say that the Congo-red test described in this case is certainly not diagnostic. I imagine that Dr. Ropes will disagree with me on that, but I believe that a not inconsiderable number of normal people have 50, 60 or even 70 per cent disappearance of the dye from their blood within an hour. An interesting discussion of this problem has recently been published.¹ I should also add that in patients with albuminuria the results must be interpreted with caution, since some of the dye is excreted in the urine. Unless one collects the urine during that

hour, one may get a false-positive test. Nevertheless, because of the fact that this patient had rheumatoid arthritis over a twelve-year period, as well as a persistent albuminuria, a hypercholesterolemia and a suggestive Congo-red test, I assume that he had renal amyloidosis. The usual sites of amyloid deposit are the kidneys, the liver, the spleen, and the adrenal glands, although it may appear in any other part of the body.

The thought occurred to me that if this patient had amyloidosis, he might also have had amyloid deposits in the thyroid gland. I had never heard of such a condition but I decided to look it up. I found an interesting article by Walker,² of Kansas City, in which he reviewed the literature describing 58 cases of what he called "amyloid goiter." In these 58 cases, only 35 patients presented true goiters. Two of these were operated on because of thyroid enlargement. I should like to suggest that as a possibility in the case under discussion. I realize that it is rather foolish to suggest a diagnosis of which one has never heard, but perhaps it is not always wise to be logical. Probably the main reason I came to that conclusion was that the presentation of thyroid problems was so unusual that the case had some sort of special interest.

DR. TRACY B. MALLORY: Will you tell us how the opinion ran on the wards?

DR. LEWIS K. DAHL: I must say that no one made the astute diagnosis that Dr. Kranes has just given. I do not believe it would add much to go into detail as to what we thought because it was so varied. No one really made the diagnosis.

DR. BERNARD JACOBSON: I do not believe the patient was too young to have a completely asymptomatic thyroid carcinoma. I also do not believe that albumin per se was the cause of excretion of Congo red in the urine. I think that albumin is present only when there is a nephrotic element. I am interested to know what the excretion in the urine was during the Congo-red test, if it was done. Do you know what the albumin-globulin ratio was in this last serum protein determination?

DR. MALLORY: The ratio was 1:28.

DR. RULON W. RAWSON: In the Thyroid Clinic there were two schools of thought: one was that this man had Hashimoto's struma, and the other that it was something that we had never seen before.

DR. KRANES: Despite the sex?

DR. RAWSON: We have seen Hashimoto struma in men.

DR. KRANES: How often?

DR. RAWSON: I cannot give the figures, but we have seen it.

DR. MALLORY: The ratio of women to men is about 4:1 in the cases that we have seen.

DR. RAWSON: The diagnosis of lymphoma was entertained, in spite of the fact that it was not written down, but we found nothing else to support it. I was among the group that did not know what

it was I should like to comment on the statement that cancer is rare at this age. We see more cancers of the thyroid gland in the younger age groups than in the older, but the tumor is usually a discrete nodule rather than a diffuse goiter. A true cancer of the thyroid gland in a large goiter such as this patient had is unusual in the young age group. On the basis of the clinical picture I believe that the diagnosis of cancer can be discarded.

Dr. Robertson, will you tell us your findings at operation?

DR. CHARLES ROBERTSON: At operation we exposed the isthmus of the thyroid gland and were at once impressed by the unusual color of the glandular tissue, which was pale, pinkish and quite vascular but did not seem to be the site of an inflammatory process because the tissues overlying it were freely movable, with no adherence to the surrounding fascial planes. The right lobe, as described in the physical examination, was somewhat larger than the left. The whole thyroid gland, however, seemed to be involved in this diffuse process, whatever it happened to be. We satisfied ourselves that the appearance in the isthmus was typical of the whole gland and removed the isthmus for biopsy. On section the gross appearance was more like that of the parotid gland or a soft specimen of the pancreas.

CLINICAL DIAGNOSIS

Subsiding acute thyroiditis

DR. KRANES'S DIAGNOSIS

Amyloid goiter

ANATOMICAL DIAGNOSIS

Amyloid goiter

PATHOLOGICAL DISCUSSION

DR. MALLORY: The biopsy specimen that we received was divided into two portions, of which one came to our laboratory and the other was sent to the Thyroid Laboratory for special study. Examination of the specimen that we received disclosed few acini of thyroid tissue and a large amount of ordinary adipose tissue, with mature fat cells and a small amount of fibrous tissue between the fat cells. When the second portion was examined histologically, it was evident that the fibrous tissue between the fat cells was hyaline and homogeneous in character, and when that was stained with methyl violet it was found to be full of amyloid. This called our attention to something that none of us was familiar with in cases of amyloidosis of the thyroid gland; it is not unusual to find large amounts of adipose tissue constituting part of the goiter. This was well described by Wegelin³ in his monograph on thyroid disease.

There is nothing in the presence of amyloid disease to rule out

course, but we can assume that the biopsy was representative. A major part of the enlargement of the gland was due to adipose tissue and not directly to amyloid deposit, but the combination of massive development of adipose tissue in the gland along with amyloid infiltration occurs too frequently for coincidence. We do not know what the relation is, but there is evidently one.

DR. KRANES: In the cases reported by Walker² that is also mentioned.

CASE 33282

PRESENTATION OF CASE

A fifty-six-year-old machinist entered the hospital because of jaundice.

Two years before admission severe pain in the right upper quadrant and jaundice developed, and a cholecystectomy was performed at another hospital, where a gall bladder containing many stones was removed. After the procedure the patient was told that the liver was enlarged. The jaundice cleared slowly over a period of two or three months, but he continued to have intermittent bouts of right upper quadrant pain and jaundice, with light stools and dark urine for six months. Then he was able to go back to work, and after a few months, he had an occasional bout of pain. During the following year and a half before admission the patient suffered from severe pain in the right upper abdomen at times, but he was able to perform his work. He had received no medical treatment for the pain. At no time did he have urinary symptoms. Physical examination showed a thin, elderly man with a feeble, soft abdomen. The liver was enlarged 6 cm. below the costal margin and was firm. The spleen was not palpable. The stools were light and the urine was dark.

Physical examination showed a thin, elderly man with a feeble, soft abdomen. The liver was enlarged 6 cm. below the costal margin and was firm. The spleen was not palpable. The stools were light and the urine was dark.

Physical examination showed a thin, elderly man with a feeble, soft abdomen. The liver was enlarged 6 cm. below the costal margin and was firm. The spleen was not palpable. The stools were light and the urine was dark.

negative except for the presence of clay-colored stools

The temperature was 100.5°F, the pulse 120, and the respirations 25. The blood pressure was 120 systolic, 70 diastolic.

Examination of the blood disclosed a red-cell count of 4,200,000, with a hemoglobin of 12.2 gm, and a white-cell count of 30,100, with 85 per cent neutrophils, 6 per cent lymphocytes and 9 per cent monocytes. The urine gave a ++ test for albumin and a +++ test for bile, and the sediment contained numerous coarsely granular casts, rare red cells and 8 white cells per high-power field. The stools were gunmetal color and slightly positive for bile and gave 0 to + guaiac responses. The serum bilirubin was 12.6 mg per 100 cc direct and 16 mg indirect, and the nonprotein nitrogen was 19 mg per 100 cc. The protein level was 6 gm per 100 cc, and the chloride 80 milliequiv per liter. The prothrombin time was 20 seconds (normal, 15 seconds). The amylase was 29 units per 100 cc.

Seven hours later the abdomen was markedly distended and tympanitic but still not tender. Peristalsis was active.

A plain film of the abdomen demonstrated dilatation of the large bowel, which contained several scybalae. Gas appeared to stop abruptly at the distal descending colon, none was seen in the sigmoid or rectum. There were several gas-filled loops of small bowel. The pelvis showed homogeneous soft-tissue density, which was thought to be compatible with a filled bladder. In the chest film the right lower lobe appeared atelectatic and diminished in size.

On the day following admission the patient's condition was considerably worse. The jaundice was deeper, and cyanosis developed. The coarse rhonchi had increased, and on the right wet bubbling rales were also heard. He was receiving penicillin and digitalis. He began to complain of pain and tenderness to the left of the umbilicus. The pain was intermittent and crampy. No spasm was associated with this tenderness, which extended over most of the left side of the abdomen and was more marked above than below. Distention increased despite a Miller-Abbott tube, the patient had passed no gas and only moderate amounts of feces by rectum. Peristalsis could not be heard. Later during the same day the blood pressure was 74 systolic, 35 diastolic.

In an oxygen tent the cyanosis was considerably relieved. By the third day the distention and tenderness were much improved, and the temperature, pulse and respirations were down to normal. The phosphatase level at that time was 12.3 units per 100 cc.

Another film of the abdomen revealed a generalized homogeneous area of increased density.

The urinary output had been steadily declining from 1200 to 500 cc, although the intake of fluid remained at 3000 cc daily.

On the fourth day all the improvement was lost, and the patient became sicker than ever. The temperature spiked to 102°F. The nonprotein nitrogen reached 98 mg per 100 cc. He was dyspneic and disoriented and pulled out the Miller-Abbott tube. The abdomen, however, remained soft and non-distended, and peristalsis was again audible. The liver had increased in size, occupying the whole upper abdomen.

The patient became comatose, with labored respirations, and died on the fifth hospital day.

DIFFERENTIAL DIAGNOSIS

DR J SYDNEY STILLMAN: May we see the x-ray films? I am particularly interested in finding out if "scybalae" is Latin for "red herring."

DR TOUFIC KALIL: These films were taken after the Miller-Abbott tube had been inserted.

DR STILLMAN: This shadow, I assume, represents one of the scybalae.

DR KALIL: There is one in the splenic flexure and one in the descending colon.

DR STILLMAN: Where is the atelectasis?

DR KALIL: The atelectasis surrounds one of the bronchi to one of the divisions of the lower lobe. The open bronchus is within the atelectatic area.

DR STILLMAN: We must first determine the nature of the liver disease from which this man suffered for two years before death, and then we must explain the cause for his rapid decline in the last of many attacks of right-upper-quadrant pain and jaundice.

We are told that two years before admission a gall bladder containing many stones was removed at another hospital and that at operation the liver was found to be enlarged. We do not know how long he was jaundiced prior to that operation, whether the common duct was explored at the time of operation or whether the spleen was found to be enlarged.

The jaundice cleared extremely slowly, indicating that the operation had failed to relieve the obstruction or the hepatic disease causing the jaundice. For the reasons that I shall present, I favor obstruction of the bile ducts by a stone or stones as the initial cause of the chain of events that led to this patient's death.

In the initial attack of jaundice, severe pain in the right upper quadrant was prominent. Many stones were found in the gall bladder, so that there was at least one chance in four that there were stones in the bile ducts also. There is no evidence that the duct was explored. Even if it had been explored we are familiar with the fact that stones are left behind in the exploration of the common duct even by the best of surgeons—the figure varies from 16 to 33 per cent of patients explored.

The subsequent course was compatible with intermittent obstruction due to stone. The man, a machinist, returned to work and presumably stayed at it. He maintained his usual weight. Occasionally,

however, he had attacks of pain in the right upper quadrant and jaundice, which apparently were not long lasting. Absence of chills and fever in the triad of Charcot is not unusual, since they are not present in two thirds of these bouts. Although itching is usually associated with obstructive jaundice, it is present in only 50 per cent of cases and in slightly less than that in parenchymatous disease of the liver. Pruritus is therefore not a real diagnostic point.

In the final attack of jaundice the first symptom was colicky pain in the right upper quadrant. The jaundice became intense, and in five days the patient became seriously ill. He was dehydrated and feverish. The liver was enlarged. There was evidence of intestinal obstruction, which I shall pass over for the present. There was a high white-cell count, as well as albumin and formed elements in the urine. The serum bilirubin was higher than one would expect in straightforward obstructive jaundice, particularly of this duration. The alkaline phosphatase was markedly elevated, which is consistent with obstructive jaundice. The prothrombin time was increased.

Because of the rapidly fatal course during this attack of jaundice it is necessary for me to consider that some additional factor adversely affected the liver. Many previous attacks, some long lasting, had occurred without causing liver failure. It seems logical to me to assume that this additional factor was an infection of the obstructed bile ducts, leading to added diffuse damage to the liver parenchyma. This complication of intermittent obstruction of the bile duct is not infrequently seen and could well explain the fever, the high white-cell count and the rapid development of the hepatorenal syndrome, which caused the patient's death. The temporary improvement might be attributed to the effect of penicillin on an undrained infection in the liver and also to a pneumonic infection. In addition, he had symptomatic relief of the intestinal obstruction, which I believe was precipitated by the scybala. The patient had been eating little as a result of the nausea accompanying this attack of pain and jaundice. He had been receiving morphine. He had not passed any fecal material. As a result of the impaction and the shock-like state, I think that he then developed intestinal obstruction, which, at least symptomatically, was relieved by the Miller-Abbott tube. Eventually, however, the liver failed as a result of the damage over a two-year period of biliary cirrhosis, the acute damage from the fresh attack of stoppage of the flow of bile and the final insult of infection. Ascites probably developed because the damaged liver was unable to inactivate the anti-diuretic hormone. Owing to the combined kidney and liver damage, the poorly understood chemical changes of the hepatorenal syndrome developed, causing death in liver disease.

I discarded the possibility that the initial attack of jaundice was due to portal cirrhosis, infectious hepatitis or some other form of liver disease because of the lack of supporting evidence in the history, physical examination and subsequent course and also because of the necessity of considering the gallstones as a purely incidental finding. I wondered whether the surgeon who operated on this man believed that the enlarged liver was really the cause of the jaundice and therefore did not search further for a possible obstruction in the common duct, either at the time of operation or later. Because a satisfactory explanation for the obstruction was at hand and because of the lack of positive supporting evidence, I did not seriously consider other causes of obstruction, such as parasites and neoplasm, primary or secondary. My diagnoses are therefore obstructive jaundice due to choledocholithiasis, biliary cirrhosis, suppurative cholangitis, biliary nephrosis, atelectasis of the right lower lobe and probably a terminal pneumonia.

DR WALTER BAUER. I agree with all the diagnoses that Dr Stillman has made, but wonder if we should entertain the possibility that a common-duct stone had eroded and that this man had a bile peritonitis, slight to begin with, but becoming severer — another explanation for the phenomena, including the dilated bowel, that were observed.

DR STILLMAN. I considered bile peritonitis but thought that there would have been other signs of peritoneal irritation, which were not reported. There were localized areas of tenderness, but shortly after the obstruction had been symptomatically relieved the abdomen became soft to palpation, which would be unlikely if perforation with subsequent bile peritonitis had taken place.

DR BAUER. One thing to remember is that the Miller-Abbott tube sometimes changes the clinical picture.

DR ROBERT R. LINTON. I think that it does in true mechanical obstruction but not in peritonitis.

DR TRACY B. MALLORY. It takes a rather large gallstone to produce gallstone ileus.

DR BAUER. I was not thinking of gallstone ileus — rather of a gallstone eroding through the common duct into the peritoneal cavity, with consequent bile peritonitis.

DR LINTON. That is usually such a slow process that the structure around the point of perforation seals itself off, so that peritonitis rarely occurs. We do not see many cases of fatal peritonitis due to this cause.

I was surprised that this man died as rapidly as he did. It is also interesting that the liver was so large, and I wonder if he had a hepatic-vein thrombosis. I do not know how one could prove it, but it is a possibility that I thought of, having seen such a case recently.

CLINICAL DIAGNOSES

Bile-duct obstruction
Biliary cirrhosis
Uremia
Bronchopneumonia

DR. STILLMAN'S DIAGNOSES

Obstructive jaundice, due to choledocholithiasis
Biliary cirrhosis
Suppurative cholangitis
Biliary nephrosis
Atelectasis right lower lobe
Terminal pneumonia

ANATOMICAL DIAGNOSES

Choledocholithiasis, with obstruction of common duct
Cholangitis, with formation of small hepatic abscesses
Rupture of hepatic abscess into peritoneum
Subhepatic abscesses
Biliary cirrhosis
Jaundice
Bronchopneumonia, massive
Operation cholecystectomy, old
Peritonitis, fibrous, localized
Adrenocortical adenoma
Pyelonephritis, acute and chronic.

PATHOLOGICAL DISCUSSION

DR. MALLORY Autopsy showed a large liver containing multiple abscesses, most of them in the left

lobe and a few in the right, as well as abscesses beneath the liver in both the right and left gutters. There was no general peritonitis. On the left side we were able to trace a communication between one of the hepatic abscesses and the peritoneal abscess. On the right side the communication was not obvious, but I think that it existed. Besides the acute infection in the liver, there was evidence of long-standing disease. The surface of the liver was practically smooth, but the organ was firm and cut with a great deal of difficulty. Microscopical study showed a well developed biliary cirrhosis, which goes with the long-standing history and the biliary obstruction. A stone, 1 cm in diameter, was present in the common duct.

The other findings were a terminal rather extensive bronchopneumonia and markedly enlarged kidneys, which I found rather disappointing histologically. They showed a mild grade of acute and chronic pyelonephritis, and possibly a little tubular swelling and degeneration of the type seen in bile nephrosis but much less than I should expect with a pair of kidneys weighing 500 gm. An incidental microscopical finding of no clinical significance was a large adenoma of the adrenal cortex.

DR. STILLMAN Did the diffuse suppurative cholangitis cause the abscesses?

DR. MALLORY The cholangitis was focal and severe in certain areas, whereas other areas were quite free of it.

DR. STILLMAN Do you think that it was the source of the abscesses?

DR. MALLORY I think that without doubt they were cholangitic abscesses.

ALLERGY TO INFLUENZA A AND B VACCINES

THE vaccines that are used for the prophylaxis of virus and rickettsial infections usually consist of suspensions of infected animal tissues in which the virus is either killed or attenuated. These types of vaccines are necessary because of the extreme parasitism of the infectious agents, which have resisted attempts to grow them in mediums that are free of living tissue. In recent years, technics have been developed for the propagation of many viral and rickettsial agents in the tissues or fluid cavities of embryonated hens' eggs. As these technics were perfected, preparations containing the tissues or fluids of infected chick embryos supplanted other types of animal tissues for the preparation of most of these vaccines.

The simplest virus vaccine and the one that is now used most extensively in human beings in this coun-

try is the one containing influenza A and B viruses. Since these viruses grow abundantly in the allantoic fluid of the developed egg, this fluid is the source of the virus that is used for the vaccine. The virus is concentrated by various methods, which involve either adsorption by and elution from embryonic erythrocytes or a similar procedure using other adsorbing agents. Centrifugation and resuspension and, more recently, concentration and purification by means of methyl alcohol have been used in attempts to reduce the amount of egg protein in the final virus suspension.¹ None of these methods have rendered the vaccines entirely free of such protein; however, although the last presumably removes a but an extremely small amount. Formalin is used to inactivate the viruses, and other preservatives are added before the vaccines are released for human use.

The possible effects of injections of influenza virus vaccines in sensitizing the recipients to egg protein and in eliciting allergic reactions in children already sensitive to this protein were summarized recently by Ratner and Untracht.² These authors also reviewed the literature on the anaphylactogenic properties of chick-embryo vaccines and recounted the various reports of serious and fatal anaphylactic reactions to injections or reinjections in human beings of vaccines prepared with chick-embryo materials. The results of cutaneous tests for sensitivity to egg proteins and to these vaccines were reviewed, and studies of their own, in which such tests were done with influenza A and B vaccine in a group of 108 allergic children, were reported.

Definite sensitivity to egg white and to vaccine was found in 11 of the patients, but only 5 were regarded as "sensitive enough to warrant circumspection and caution in the use of the vaccine." It was calculated that serious egg allergenicity could be expected in about 1 in every 200 children, and probably somewhat less often in adults. To safeguard the seriously sensitive persons, it is not sufficient to obtain a history of allergy to egg, for often this is vague. A test dose of vaccine should be given before each and every prophylactic injection, and perhaps a test should also be made with egg white. If both or either is strongly positive, the patient is seriously sensitive and vaccine should be

withheld If a systemic reaction results from the test dose, vaccine should be withheld unconditionally

Thirty-nine patients gave only suggestive reactions to one or more of the egg proteins These children were mostly eight to thirteen years of age and were considered to have moderate to mild sensitivity, which at the time was probably not of clinical significance Some of these suggestive reactors were shown to be sensitive to formaldehyde and not to egg

The authors expressed the belief that a history of allergy per se is of no significance, since allergic persons without specific sensitivity to egg protein are no likelier to have a reaction from the vaccine than are nonallergic persons Furthermore, they are of the opinion that a lack of history of sensitivity to egg is of questionable value, since sensitivity was occasionally demonstrated in such persons by skin reactions and even by constitutional reactions to injected egg protein

Ratner and Untracht do not mention the increased danger of reinjection in such cases, a possibility that should be seriously considered The immunity following the injection of influenza vaccines is short-lived, and reinjections at least every two or three years and perhaps again at the first evidence of an outbreak seem to be the only long-range method of effective control with the vaccines now available The danger of such frequent reinjections must be weighed against the possible benefits Two recent developments may help to minimize these dangers The first has already been mentioned—the perfection of vaccines from which most of the protein has been removed¹ The second is the demonstration of antibody responses to single intracutaneous injections of 0.1 cc of vaccine that are similar or superior to those resulting from single subcutaneous injections of 1 cc of the same vaccine.² Possibly intracutaneous vaccination will prove effective even with diluted virus, in which case the amount of foreign antigenic protein may be reduced still further and vaccination may then be undertaken repeatedly with safety Only the results of a large and controlled experience will prove whether these possibilities are attainable

A fatal reaction to the injection of influenza vaccine, recently reported by Curphey,⁴ serves to illustrate the importance of this problem This followed the subcutaneous injection of 0.5 cc of influenza A and B vaccine in a three-and-a-half-year-old girl The only personal history of allergy was an attack of urticaria ascribed to aspirin The family history was negative, and all members of the family received the same vaccine without reaction The allergic reaction developed four hours after the subcutaneous injection of the vaccine and was characterized by convulsions, abdominal pain, vomiting, hemorrhagic phenomena, hyperthermia and, finally, respiratory arrest and death In discussing this reaction Salk⁵ suggests that it was due to the amount of virus given and that such reactions could be avoided by the proper adjustment of the dose given to children

THE BEWILDERED AGE

THERE seems to be a strong tendency, increasing as time goes on, to shape the structure of our lives to that of an inverted pyramid We continue to broaden our activities and our problems of survival in every direction, while still trying to balance on the same uncertain point of contact with the earth The result has been increasing insecurity and instability, reaching down into the lower age groups The American home does not offer all that it should in effort and understanding, and the insecurity of the child may often be a reflection of the insecurity of the parent.

Social, academic and economic pressures have reached too dangerously near a breaking point. Competition has become too keen, and standards have been set too high for many adolescents, who need more and better guidance than they have been getting

This need is recognized by the schools, and recommendations for psychiatric study and treatment are

not infrequently made, but with little apparent realization of the likelihood that in numbers alone the available psychiatric personnel would be entirely inadequate for the job. There is scarcely a person alive of any age who does not occasionally need wise guidance and counsel on matters of personality and social adjustment, but to try and put even a moderate percentage of these into the hands of psychiatrists would at present be impossible.

The need for highly trained and responsibly applied psychiatric help is often grave, and the probability should also be recognized that many of these young persons are failing to receive any form of help because of a technic that lack of man hours and lack of money put beyond their reach. If all the young people who need guidance in human relations are to receive it, less time-consuming and more economical technics are necessary, and a share of the guidance should, if possible, become part of the family obligation.

Guidance in the development of the child's personality should be assumed more frequently than it is now by those who are in the most strategic position to give it because of their acquaintance with the child and who are qualified to add a certain amount of technical knowledge. The specialist should be reserved for the special cases, and guidance should be freely available to the rest from such sources as the family doctor or pediatrician, the pastor and, in many cases, the teacher. The parent should be made a partner in the counsel, not ignored as is too often the case, and the schools themselves, which are so intimately concerned with these difficulties, must be better prepared to help in their solution.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

CLARKE — Joshua W. Clarke, M.D., of Attleboro, died on March 24. He was in his seventy-seventh year.

Dr. Clarke received a medical degree from University of the South, Medical Department, Sewanee, Tennessee, in 1901 and from Medico-Chirurgical College of Philadelphia in 1910. He was chief of obstetrics, Sturdy Memorial Hospital, and was a member of the New England Obstetrical and Gynecological Society and a fellow of the American Medical Association.

His widow, two adopted sons, two stepsons and two sisters survive.

DONOVAN — Thomas R. Donovan, M.D., of Fitchburg, died on March 30. He was in his sixty-fifth year.

Dr. Donovan received his degree from Tufts College Medical School in 1909. He was a member of the staff of the Burbank Hospital and of the New England Obstetrical and Gynecological Society and a fellow of the American College of Surgeons and the American Medical Association.

MEDICOLEGAL ABSTRACT

Contempt — and the Doctor's Oath*

I Swear by Asclepius, by Hygiea, by Panacea

Of all government's powers, those most important to its successful operation are probably the power to tax and the power to maintain military forces (including the power to conscript). For successful administration of government, on the other hand, the power of eminent domain, usually mentioned in this regard, is probably second to the power to punish individual disobedience of governmental orders (a part of the police power). This latter power is of course exercised in the imposition of sanctions for deviation from the governmental ("public" in a republic or a democracy) policy embodied in the criminal laws, but in a way closer to the dignity and welfare of the government (as distinct from the state operated and administered by it), this power is manifested in the punishments awarded for disregard of individual commands of governmental agencies.

However precisely the criminal laws may be drawn, they cannot hope to anticipate all the situations in which it may become important for an individual to do an act, or to refrain from some act, at the behest of government authority. Some power must exist in the government to support its officials in all those situations, and that power must to be effective be capable of summary application.

The individual's offense against this governmental interest may take the form of a mere overt general disrespect which is most important in the care of agencies and governments whose dignity is of paramount importance, and *lesé majesté* has been, and is still today, a serious offense in governments resting on a strong centralized authority, particularly where that authority is concentrated in one person.¹ In this Country, however, criticism of or disrespect to, the Government or its officials has come to be thought of as a relatively trivial matter. This is particularly true as the attitude has grown in some circles that to be flippant about responsible public officials, to manifest, cleverly, scorn and disrespect for their personal characteristics (if they are of different political philosophies) and to reflect discredit on the traditions they represent, is more than fashionable — it is almost *de rigueur*, it is the countersign of the true intellectual.² Only in the case of the courts has the requirement of respect persisted, and flagrant abuses of it are still not tolerated, even today.³

Whether the requirement is of the maintenance of a respectful attitude in general or of obedience to a specific order, a violation is classified as a contempt. To indicate the authority of the agency concerned, a contempt may be punished "criminally," by summary action (such punishment not being con-

*This article, by C. A. Peairs, Jr., is reprinted, by permission, from the May, 1947, issue of the *Boston Bar Bulletin*, to which the reader is referred for documentation, largely omitted in this version.

sidered a criminal proceeding within the meaning of such Constitutional guaranties as that of trial by jury), or, in a "civil contempt" proceeding, punishment may be ordered conditionally, using it as a threat to induce an obdurate individual to purge himself of his contempt, by recanting, by apology or by obedience to the order previously disregarded.

The governmental power to punish for contempt is widely used by courts of chancery to enforce their decrees, such cases usually involve only civil contempt, a criminal contempt is of course involved if the authority of the chancellor is flouted, but it is usually disregarded unless some act of contempt other than the mere failure or refusal to obey the decree is involved.

Second only in frequency to the chancellor's use of this power, just described, is that of various governmental agencies to compel attendance and truthful testimony by witnesses at various official inquiries, and having discussed the background of the existence of this power, it is my purpose in the remainder of this note to discuss one or two specific problems in its application.⁴

1 It is obvious that facts necessary as a basis for meting out of justice or for establishing legislative policy cannot be obtained where hostility or lack of co-operation is encountered locally, unless the power exists to punish failure or refusal to attend inquiries or to testify. This power is most commonly thought of in connection with judicial bodies⁵, it has been recognized as to courts of chancery since the development of the subpoena in c 1375, and as to common law courts since the *Statute of Elizabeth*⁶. There resides a power in the legislative and executive branches of the government, as well, to summon witnesses to testify, and in the case of the legislature to punish disregard of such summons, but it is not clear that the executive has the latter power. The category of courts possessing the power to punish for contempt includes appellate courts and courts of general jurisdiction, but not inferior courts. A grand jury is, however, an agency whose summons will clearly be enforced by contempt proceedings in the appropriate court, since the grand jury's investigation is one of the basic forms of judicial inquiry by a court of general criminal jurisdiction.

In any case in which the oath may be administered and the question may be asked, if it is answered untruthfully, a criminal penalty for perjury may be imposed, but if the witness refuses to answer the question at all, the criminal law provides for no remedy, in the absence of a statute penalizing mere refusal or failure to answer.⁷ In addition, the delays involved in the standard criminal proceeding render it unsatisfactory in a situation where prompt action is required, not to mention the undesirability of a remedy requiring a jury verdict, which cannot be relied on in an area (geographical or legal)

where witnesses are recalcitrant. The summary process of commitment for contempt, not a true criminal proceeding even if criminal contempt is involved, is the device worked out to meet this need, and is admirably designed to impress all concerned with the weight of governmental authority which can be brought to bear when the need arises.

2 In almost perfect balance with the governmental interest in being able to question people and to rely on their answering, and truthfully, is the interest of the individual in not being subjected unjustifiably to official examination (that is, unless there is sufficient necessity to overbalance the inconvenience caused him in the case), and from being subjected to undue pressures to answer questions on matters not the proper concern of the questioning agency.

A basic safeguard of individual interests of this sort is found in the Constitutional prohibitions of cruel and unusual punishments, which means that today fine and imprisonment are the only means which can be employed, with official and public sanction, to make a reluctant witness talk. There are other required procedures to prevent intimidation of witnesses, but the limitations on the types of coercion which may be employed are the most important in this respect.

In addition to these purely procedural safeguards, there are a number of limitations on the things which a witness can be forced by any means to tell the so-called privileges not to testify. Of these the most important category, Constitutionally created, is that against self-incrimination. This privilege is taken for granted today, as having existed from time immemorial, but it did not exist, nor was it thought of, during the centuries of growth of the common law.⁸ Both ecclesiastical and royal courts employed the inquisitional oath, developed under Pope Innocent III in the Thirteenth Century, and though the jurisdiction of the former suffered with the English Reformation under Henry VIII and thereafter, the royal courts did not even thereafter consider such proceedings objectionable because of their origin. It was not until the time of the fall of Charles I that the oath, officially administered to a criminal defendant to require him to testify as to his own guilt, was declared improper (first in *Libburn's Trial*, 1637-1645, and in a number of cases of lesser importance during the same period and shortly afterward), and fell with the Star Chamber Court (a special session of the Privy Council for political cases), its chief remaining employer. Even then, the privilege was limited to the defendant on trial, and was not extended to witnesses not on trial until *Reading's Trial*, in 1679. Under it neither a party nor any other witness in any proceeding, civil or criminal, or in any preliminary official investigation, may over his objection be compelled to give testimony or other evidence which might involve him in criminal liability, as distinct from civil liability,

or from mere public infamy or disgrace. It does not afford protection against disclosure of crimes of others.

Disclosure of information of the affairs of others, to their disadvantage or against their will, is prevented by a different class of privileges, not generally based on Constitutional policy, relating to certain categories of confidential communications. The most important privileged communication of common-law origin, dating back about four centuries, is that between client and attorney. It prevents disclosure by either client or attorney of any confidential information given by the client to the attorney as an attorney, so long as the client may object to such disclosure, but does not apply to information the attorney may obtain from others, or in another capacity than as an attorney.

There are other communications privileged at common law, and some additional privileges created by statute, but most of them affect public or quasi-public officials. One important exception is the privilege applied by common law to private communications between husband and wife, made during the marriage. This privilege, under modern statutes, is generally considered in connection with marital non-waivable disqualifications to testify.

3 Every member of the medical profession considers himself spiritually obligated to at least the substance, in a modern context, of the Hippocratic Oath,⁹ pertinent portions of which are as follows:

I swear by Apollo Physician, by Asclepius, by Hygiea, by Panacea, and by all the gods and goddesses, making them my witnesses, that I will carry out, according to my ability and judgment, this oath and this indenture. And whatsoever I shall see or hear in the course of my profession, as well as outside my profession in my intercourse with men, if it be what should not be published abroad, I will never divulge, holding such things to be holy secrets. Now if I carry out this oath, and break it not, may I gain forever reputation among all men for my life and for my art, but if I transgress it and forswear myself, may the opposite befall me.

Under the policy of this oath, a privilege has been applied to communications between physician and patient, under statutes enacted in many American states, though at common law no privilege attached to private confidences in general, and this rule was applied to confidential communications by patient to physician. There appears to be little logical justification for the privilege, statutory or otherwise, other than the concern of physicians for the honor of their profession — an extralegal consideration, and such statutes have not been passed in Massachusetts or in any other New England state.

The effect of the existence or non-existence of this privilege is easy to see where a case is already in progress, and the physician is called as a witness, but there may be some important collateral effects, even where no case is pending. Suppose the physician learns that a crime has been committed, does he owe the same duty as any other citizen, to notify police authorities, or the prosecuting attorney, or

to testify before a grand jury? Or does he have a limited duty, varying with the seriousness of the crime of which he learns?

Suppose, for example, that the physician learns that a murder or rape has been committed, through his treatment of the only available witness, as a patient. At least under Massachusetts law it is clear that he should notify the authorities that a crime has occurred. But does his duty stop there? May he say to the police "A crime was committed at such and such a time and place. There! Now I've told you, my hands are clean. It's up to you to find out the rest. I know where the evidence is, but I won't tell — physician's oath, you know. The name and address of my patient are confidential. I couldn't tell you *that*?"

The problem would seem to be most clearly presented in the rape example. Not only is that the case in which the physician is most likely to acquire such information, but there, if he does not give full data to the authorities, is the greatest chance for a crime to go unpunished, for in a rape case the *corpus delicti* (in the broad sense) is much less likely to be discovered and recognized without the physician's help.

It seems that in a proper proceeding, before a court, a grand jury or other authorized agency, the physician can be compelled to speak, and is in contempt if he refuses to speak, and may be committed until he does speak. The only remaining question is one of policy, as to how far the court or grand jury should go in exercising the contempt power to further a prosecution or investigation where there has been no complaint.

It may be urged that even though there is no physician-patient privilege in Massachusetts, enough of the policy may be imported from the many states which do have such statutes to grant the physician a little more latitude than a layman in limiting his testimony. This contention suffers, however, in the light of the criticism to which this privilege has been subjected, and it appears difficult to make out a case for even a semi-privilege by decision, where the legislature has not spoken.

The same case may also be considered as depending partly on the public policy of the law of rape. If there remains in the law even vestigially the ancient common-law policy that the whole matter might be cured by a marriage, and that the offense was no felony, but only a misdemeanor, if no complaint was made by the woman injured, then it may be argued, if the woman does not wish to come forward, that the physician is not hindering prosecution of so serious a crime, after all. But if, on the other hand, rape is considered primarily as an offense against the Commonwealth, and if the witness who fails to prosecute is considered as contributing to the threat to other women, which exists so long as the offender is at large, then the silent physician is equally contributing to that same threat to the peace.

of the Commonwealth, and his silence is a serious matter, and it would seem that this is the correct view to take of the matter.¹⁰

The patient's position in the matter does not justify the physician's refusal to speak. She is not incriminated, unless her failure to complain is treated as making her an accessory, and however logical that might be, it is not a practical consideration. The only interest she can claim in the physician's silence is that of freedom from a distasteful or humiliating contact with the inquiry. But her right of privacy does not extend so far, she has become involved, *nolens volens*, in a crime, and owes a citizen's duty to participate in the administration of justice. If the facts are learned by the authorities she can be summoned as a witness, owing the general duty to testify described above. She can even be compelled to undergo physical examination or inspection in open court, to corroborate or discredit her testimony. Her position, then, is such that the physician can not be said to be protecting her legal interests, though it can be appreciated that she may personally desire not to be involved.

What of the physician's professional position? Is he faced with a dilemma, of choice between legal sanctions, if he does not speak, and professional censure, if he does? The answer seems to be that his professional ethics bind him only to remain silent in general conversations, and that compulsory testimony in an official proceeding constitutes no violation of his code of ethics.

There seems to be, then, no private interest, in the case of the physician, sufficient to overbalance the public interest in full and truthful testimony on such serious matters, and since the public interest is paramount in these cases, it seems clear that the power of the court to punish for contempt may properly be exercised in such case, and that the physician may be kept in confinement until he discloses the information which the public interest demands.¹¹

Lewis (official citations not available at this writing) *Herald Tribune* (New York) *Barron Herald* March 8 1947 *Time* March 17 1947. A close study of Mr. Lewis' conduct since these proceedings were commenced may prove profitable in an inquiry as to just how much a court will permit in overt manifestations of disrespect without acting today.
- 4 Many readers will of course recognize the relevance of these comments to a recent Superior Court case which gained some newspaper notoriety and was the basis of the *Bulletin's* request to the author to prepare this note.
- 5 It did not always reside in them, but was developed after the ancient concept of the juror as an informed witness was replaced by the modern notion that the juror must be as ignorant as possible (of the case) in order that he may be as impartial an arbiter of matters of fact. Under the older system a witness who was not a juror was something of an interloper, and only during the sixteenth century came to be thought of as essential to the trial of fact. A full discussion of the history of the general testimonial duty is found in *Wigmore on Evidence* (1940) § 2190. Wigmore's work as well as Lauch's *Handbook of Massachusetts Evidence* has been drawn on heavily as a source of authority for evidentiary points mentioned herein.

- 6 1562-1563 imposing a penalty and a civil liability for refusal for a witness to attend after summons. That this right belongs not only to the state but also to the individual needing the witness's testimony is shown by Constitutional and statutory guarantees to parties of proofs favorable to them.
- 7 Punishable in Massachusetts under G. L. c. 233 §§ 5 and 11 (apparently under the contempt power recognized by the statutes; no penalty is specified under the latter section for failure to testify as distinct from failure to attend) and c. 277 § 69 (no penalty is specified by this section either).
- 8 This conclusion is drawn from Wigmore § 2250 "History of the Privilege (against Self Incrimination)" and the historical sketch which follows is largely condensed from that section.
- 9 *Hippocrates, Works* v. 1, p. 299, taken directly from Will Durant, *The Life of Greece* (1939) p. 347.
- 10 Popular feeling on this subject shifts from time to time. It would be interesting to see a study of percentages of convictions in rape cases, before and after the recent Coombes case (*Time*, March 17 1947). Boston newspaper reports, March 1947, and the resulting wave of hysteria as to juvenile delinquency and administration of correction work.
- 11 The witness who gets into trouble for improperly failing to testify even after reading this note, may find solace, or possibly even assistance in the precedent of Miss Beckman as related by Arthur Trelo.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

POLIOMYELITIS AND TONSILLECTOMY

It has been well established that when poliomyelitis is contracted in the days immediately following the removal of the tonsils and adenoids the involvement of the cord extends higher into the midbrain and the bulbar type of the disease results. This type presents difficult therapeutic and medical-care problems, which, if not adequately met, often lead to a fatal termination.

Recently, in years of high prevalence of poliomyelitis, the Department has issued a warning that elective tonsillectomies should be postponed until incidence of the disease declines to low levels.

Surgeons and hospitals have been inquiring this year regarding the date on which the Department would again issue the warning. Unfortunately the date cannot be determined beforehand. In fact, in some years there has been no good basis for issuing such a warning. For instance, in 1938, 1940 and 1942, when 18, 45 and 36 cases of poliomyelitis were reported respectively for the whole state, no interruption in tonsillectomies was indicated except in a few localized areas. On the other hand, in 1945, with 527 cases, and in 1946, with 379 cases, it seemed wise to suggest postponement.

In most years there is little tendency for poliomyelitis to become relatively prevalent until after August 1. It is a good plan, therefore, to schedule as many elective tonsillectomies as possible before that date, to interfere as little as possible with the program of scheduling necessary operations. After August 1 further operations should be cancelled as soon as it becomes evident that the disease is becoming prevalent in the vicinity of the hospital or of the place of residence of the prospective patient.

BOOK REVIEWS

Motor Disorders in Nervous Diseases By Ernst Herz, M D , and Tracy J Putnam, M D 8°, cloth, 184 pp, with 250 illustrations New York King's Crown Press, 1946 \$3 00

The book is based on a teaching film that shows the methods of examination and the gross motor disturbances in certain diseases of the nervous system. Particularly well demonstrated are abnormal involuntary movements, disorders of gait and co-ordination, skilled acts and dysfunction of the muscles supplied by the cranial nerves. The illustrations, mostly taken from the film, are excellent, and the book should be of considerable value to medical students and interns. In many places the pictures from the basic film are supplemented by diagrams and other illustrations, thus making the book useful by itself. The entire 16-mm film may be obtained at a cost of \$450, or a portion covering a separate subject may be purchased.

Modern Management in Clinical Medicine By F Kenneth Albrecht, M D 4°, cloth, 1238 pp, with 237 illustrations Baltimore Williams and Wilkins Company, 1946 \$10 00

This is a new kind of book on clinical medicine. It is intended as a ready reference volume for the doctor's office rather than a textbook for his library. The author has succeeded in compiling a large number of medical facts, old and new, obtained from many sources of the vast medical literature. He presents to the medical profession—in a condensed and simplified manner—the new advances and techniques in the practice of medicine.

The first chapter deals with a detailed outline of recording a case history. This is followed by an adequate chapter on malnutrition and vitamin-deficiency diseases. Then follows the systemic diseases in the usual order. The aphorisms on acute appendicitis and the table giving the differential diagnosis of acute abdominal pain, as well as the author's remarks on the pitfalls in the diagnosis of acute abdominal conditions, are excellent. Most of what is known about blood dyscrasia is presented in a simplified form in the chapter on diseases of the blood and blood-forming organs. This is true of the chapters that follow. The author gives not only the essential signs and symptoms in the diagnosis of a certain disease but also the differential diagnosis. And what is more important is that treatment is described in detail in each case. Of special interest to many a physician at present is the chapter on tropical diseases of postwar importance. Nor is the youngest branch of medicine—geriatrics, the care of the aged—forgotten. In the chapter on diagnosis and treatment of common skin disorders the author does not mention pemphigus, which is neither rare nor hopeless. The book ends with a description of clinical laboratory methods in medicine.

The practicing physician will find this volume a valuable companion near his office desk. Its twelve hundred pages contain much valuable and practical information, ready at a glance when needed.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Juvenile Delinquency A critical annotated bibliography By P S deQ Cabot, Ph D, director of personnel research, Rexall Drug Company 8°, cloth, 166 pp New York H W Wilson Company, 1946 \$3 75

The compiler has brought together in this bibliography over nine hundred references on juvenile delinquency for the period 1914-1944. The arrangement is by author, and all references are annotated. The list is selective, including only references of value in research, prevention and treatment. The volume should be in all libraries, including medical libraries.

The Nervous Child By Hector Charles Cameron, M A, M D (Cantab), F R C P (Lond), consulting physician to the Children's Department, Guy's Hospital Fifth edition. 12°, cloth, 252 pp, with 8 plates London Oxford University Press, 1946 \$3 00

In writing this small popular book the author deals with the influences that mold the mentality of the child and shape his conduct. First published in 1919, the book has been printed twelve times in five editions. The various aspects of the subject are covered for children of all ages from infancy to adolescence. There are chapters on the various signs of nervousness, including appetite and indigestion, sleep, enuresis, masturbation and metabolism, and management and conduct, including sexual matters. The text is well written and well organized. The book is published in every way and should prove useful to pediatricians and neurologists, as well as the general practitioner.

Guide for the Tuberculous Patient By G S Erwin, M D, medical superintendent, Liverpool Sanatorium, Frodsham Cheshire, England American edition revised and edited Henry C Sweany, M D, medical director of research, Municipal Tuberculosis Sanatorium, Chicago 12°, cloth, 126 pp New York Grunc and Stratton, 1946 \$1 50

This popular manual is written for the sanatorium home patient and provides him with the necessary knowledge of the disease so that he may intelligently understand the physician's approach to his individual problem. The emphasis is on treatment, and public-health aspects and pulmonary tuberculosis are briefly discussed. Dr Sweany has adapted the text to American practice.

What is Heart Disease? A handbook for the heart patient By William Hyatt Gordon, M D, head of Medical Section, Lubbock, Memorial Hospital and Clinic, Lubbock, Tex. 12°, cloth, 114 pp New York Grunc and Stratton, 1946 \$2 50

This small book for the sufferer of heart diseases is intended to supplement the advice of the physician. The structure and action of the heart are explained, and its diseases and treatment are discussed from the patient's point of view. Simple diet lists are given in an appendix.

Nursing Care in Chronic Diseases By Edith L Marsh, R N, S C M, superintendent, Cuyahoga County Nursing Home, Cleveland 8°, cloth, 237 pp, with 28 illustrations Philadelphia J B Lippincott Company, 1946 \$3 00

Miss Marsh has written an excellent manual on the care of the chronic patient and has illustrated her text with case histories of various types of chronic disease. In a final chapter she discusses frankly the deficiencies in the present care of the chronically ill and makes recommendations for an expanded program for Cleveland. The volume is well published in every way and should be in all nursing collections.

NOTICES

LECTURE SPONSORED BY THE CHILDREN'S HOSPITAL

At noon on Wednesday, July 23, Dr William Feldman, of the Mayo Foundation, will give a lecture entitled "The Evaluation of Substances Effective in Vivo against the Tubercle Bacillus." The address will be delivered in the amphitheater of the Peter Bent Brigham Hospital under the auspices of the Children's Hospital. All members of the medical profession are cordially invited to attend.

ANNOUNCEMENT

Dr Edward Blank announces the reopening of his office for the practice of psychiatry and neurology at 733 West McDowell Road, Phoenix, Arizona.

MEDICAL GROUP PRACTICE IN THE UNITED STATES*

I Introduction

G HALSEY HUNT, M.D.†

FOR many years, notably since the report of the Committee on the Costs of Medical Care¹ in 1932, there has been considerable sporadic discussion of group practice, but critical factual analysis of the subject has been meager and limited. World War I apparently acted as a major stimulus for the formation of many medical groups during the immediate post-war years, and there is evidence that a significant expansion of group practice is also following World War II. The responses to the questionnaire submitted by the American Medical Association to medical officers in the armed forces in 1944 indicated that 52 per cent of physicians wished to engage in private group practice after the war.² Furthermore, interest in all the technical and social aspects of medical care is at a high pitch, both among the general public and among the professions involved, and shows signs of becoming even intenser. For both these reasons, the time seems ripe to undertake a factual analysis of medical group practice on a scale and of an intensity never before attempted.

DEFINITIONS

It must be understood at the beginning and kept in mind throughout the discussion that the terms "medical group practice" and "group practice" are generalized, attaining comprehensible and expressible meaning only when they are properly qualified and placed in the appropriate frame of reference. In other words, the unqualified term "group practice" means only that two or more physicians are collaborating to some extent in practicing medicine. As a result, some discussions of group practice include organized hospital staffs and industrial and co-operative medical-care plans, and sometimes even the grouping of several physicians' offices in one building without other organized financial relations. At the other end of the scale, consideration of group practice is sometimes limited to medical organiza-

tions owned by one or more of the practitioners in which all income is pooled and divided among the physicians according to a prearranged formula.

An example of the inclusive definition is provided by Moore,³ as follows:

It is generally understood that group practice consists of a number of physicians and dentists who combine their professional services, skills and financial resources, to practice the prevention and treatment of disease. These practitioners use common offices, facilities and professional equipment. They employ in common, subsidiary personnel for administrative and clinical purposes.

Clark and Clark⁴ define the term as "the systematic practice of medicine by groups of physicians working in close professional co-operation and utilizing common equipment and technical personnel."

Rorem⁵ and the Bureau of Medical Economics of the American Medical Association⁶ followed much more restricted definitions in their respective studies. The former defined "private group clinics" by the following characteristic features:

1. Its physicians engaged in co-operative and contiguous medical practice, use many facilities in common particularly office space, laboratories, and medical equipment.
2. Its physicians—all or most of them—are associated with the clinic on a full time basis.
3. Its services include two or more medical specialties and an attempt is usually made to hold available complete facilities for the patients accepted by the clinic, although some groups avowedly exclude from their services such specialties as obstetrics, ophthalmology, or dentistry.
4. Its patients are the responsibility of the entire group not merely of individual physicians although when consultations and special diagnoses are not required, one practitioner may alone treat a given case.
5. Its income is "pooled" and its practitioners have little or no direct financial relationship with patients.
6. Its members determine individual incomes by contract among themselves, rather than directly from their services to patients.
7. Its administration is carried on by a business man rather than a physician, as far as non-medical matters are concerned.
8. Its credit investigations and collection policies are the specialized functions of a business manager rather than the incidental concerns of the several practitioners.

The Bureau of Medical Economics of the American Medical Association included in its 1940 study only the groups with the following characteristics:

*Published with the permission of the Surgeon General, United States Public Health Service.
†This is the first of a series of reports summarizing the findings of a study of medical group practice initiated by the Division of Public Health Methods, United States Public Health Service, early in 1946.
†Senior Surgeon, United States Public Health Service.

(Notices continued on page 20)

tion that causes real confusion is the actual time of transition in a given group from the service to the reference category.

PREVIOUS STUDIES

The literature dealing with the factual aspects of group practice is meager. Rorem⁴ studied fifty-five private group clinics for the Committee on the Costs of Medical Care by interviews and mail questionnaires and obtained opinions concerning group practice from ninety-seven physicians in thirty-four clinics and from one hundred and thirty-four physicians in independent practice in twenty-two cities in which group clinics were located. The Bureau of Medical Economics of the American Medical Association published reports in 1933⁷ and 1940⁸ that summarized the findings of questionnaire studies addressed to secretaries of county medical societies and medical groups. The second of these studies was considerably more extensive than the first, and was reported in a seventy-page pamphlet. Like the other studies cited, it dealt with the number, size and distribution of private medical groups, with their physical facilities and administrative practices and with the opinions of physicians in both group and individual practice. In addition, the report devoted considerable discussion to the historical development of groups and of group practice, correlating the latter to the outrunning by population growth of the medical, hospital and laboratory facilities available in the rapidly growing parts of the country. The report also champions the general practitioner as the only doctor necessary in 85 per cent of all illnesses, questions the value of service groups while stressing the belief that reference groups fulfill an important function adequately and economically and in general holds that, in a medically well developed area, group practice is less effective in providing high quality medical care and in stimulating the professional advancement of the physicians than are general hospitals with organized staffs, independent specialists and well equipped laboratories.

American Medicine,⁹ published by the American Foundation in 1937 and summarizing narrative replies from two thousand practitioners to a series of questions concerning medical practice, devotes a chapter to group practice. The many comments cited run the gamut of approval and disapproval, but the editor concludes that the weight of opinion is slightly in favor of group practice.

The first efforts to determine the kinds and amounts of medical care furnished by group clinics were made in 1939 and 1940 by Goldmann¹⁰ and by Clark and Clark,¹¹ who conducted intensive interview studies of seven and fifteen groups respectively. In addition, the Clarks studied samples of the medical records of several groups in an effort to estimate "the degree to which advantage has been taken of the clinic's facilities for diagnosis and

treatment and the extent to which coordination of the various services has been achieved."

Besides these studies there have been many articles by members of groups and by other observers.¹²⁻²¹ These are of value in conveying the tone and color of group practice, but are for the most part subjective impressions or accounts of personal experiences rather than an impartial evaluation of the general phenomena of group practice. A number of articles have dealt with the fiscal and administrative aspects of the subject, with little consideration of the actual medical practices.²²⁻²⁶

CLAIMS AND CRITICISMS

It may be of value at this point to attempt an enumeration and classification of the chief points on which differences of opinion exist regarding group practice. The warning of the American Medical Association⁸ report must be kept in mind throughout this discussion: "It should be evident by this time that generalities in regard to any phase of group practice are dangerous. Nowhere is the opinion of a shrewd French writer more justified than 'No great generalization is ever wholly true — not even this one.'"²⁷ Few observers of group practice would subscribe without reservation either to the list of advantages cited below or to the list of disadvantages, the nature and ramifications of the subject are such, however, that few observers remain at dead center, balancing advantages and disadvantages evenly. It seems to be a subject on which most students take up a fairly well defined position, for or against, and draw on the rival arsenals of ideas listed below for their verbal ammunition.

The principal advantage claimed for group practice is that modern medicine is so complex that no one physician can comprehend²⁸ the niceties of diagnosis and treatment, that as a result of this situation, most sick people — if they are to get the best medical care — must be seen by more than one physician and that organization of physicians into groups is the only way in which this can be done efficiently and economically. It is claimed that physicians working together in a group are stimulated to keep up with medical progress more than physicians in individual practice and that each physician, constantly subjected to the informed appraisal of his fellows, has more incentive to do his best work and is less likely to develop slipshod habits of medical practice. The ease and value of consultations is enhanced because the consultant has the patient's whole medical record before him and can more quickly and efficiently bring his own special knowledge to bear on the case. Young physicians, especially those with specialist training, are enabled to concentrate from the beginning on the type of work in which they have been trained, avoiding not only the struggles of establishing a practice but also the loss of skill from disuse that is often the fate of the young specialist. On the

- 1 There must have been at least three physician members
 - 2 The receipts from medical practice must have been pooled in some manner and then redistributed to the members according to some previously arranged plan
 - 3 "Closed staff" hospitals were not included unless the members of the staff pooled the income received for services outside the hospital
 - 4 Purely "diagnostic" groups which receive only referred cases were excluded
 - 5 "Industrial" groups which furnish medical services to a single industry, and thus to only a limited group of the generalized population, were omitted
- Groups that have become notorious for their exaggerated advertising and solicitation, and whose members have, therefore, been excluded from organized medicine, have been omitted from this study

In the absence of a generally accepted definition of group practice, everyone who studies or discusses the subject must set up his own standards and limitations. The present study excludes, tentatively and for the time being, organized hospital staffs in which the physicians participate on a voluntary part-time basis, groups of physicians practicing the same specialty and groups of physicians who, although having contiguous offices and possibly even using secretarial and other personnel on a "shared overhead" basis, have individual financial relations with patients.

The reasoning back of these exclusions may be summarized briefly. Organized hospital staffs, although they may be considered the prototype of group practice, represent a part-time activity from which the physicians do not make their living and that influences only indirectly the major portion of their work. Groups of physicians practicing the same specialty are omitted because they constitute only a quantitative rather than a qualitative increase over the practice of a single person. The third category, comprising what may be called "informal groups," may well be a proper subject for future research but is omitted for the time being, until more is known about the characteristics of the more formally organized groups.

Classification of groups according to sponsorship and type of practice is possibly a more fruitful occupation than attempting to set up an iron-clad definition of group practice. The following are the terms and definitions that are used in the present study.

A Classification according to ownership or sponsorship

- 1 *Private groups* Ownership and authority vest in one or more of the physicians who are practicing together as a group
- 2 *Industrial groups* Ownership and authority vest in a commercial company, with the employees of the company as the principal, if not the only, patients
- 3 *Consumer groups* Ownership and authority vest in an organization consisting of potential recipients of medical care. These may be employees of a single company, a consumers' co-

operative, a labor union or a similar organization

4 *Hospital groups* Ownership and authority vest in a nonprofit voluntary community hospital

5 *Medical-school faculty groups* Ownership and authority vest in a university or medical school, or in one of its subsidiaries or components

6 *Government groups* Ownership and authority vest in a federal, state or local governmental agency

B Classification according to scope and type of medical services offered

1 *Service groups* Those whose principal activity is the furnishing of complete medical care to a continuing clientele. (This term, although it has been used in previous discussions of group practice, is not altogether satisfactory, since it is not sufficiently descriptive and, in addition, implies falsely that reference groups do not give service. Suggestions for a better term are welcome.)

2 *Reference groups* Those whose principal activity is the furnishing of specialized care to patients referred to them by outside physicians, usually for a single episode of illness, and that ordinarily do not undertake to furnish complete medical care to a continuing clientele.

3 *Diagnostic groups* Reference groups that give little or no treatment.

Even with these broad yet apparently distinctive classifications, ~~several~~ groups possess features that make precise definition difficult. For instance, a group may be composed exclusively of members of a hospital and yet be a private enterprise for business purposes, with the power vested in the hands of a few. If the group is organized as a partnership, the power is shared among the partners. If the group is organized as a corporation, the power is vested in the hands of the stockholders. If the group is organized as a trust, the power is vested in the hands of the trustees. If the group is organized as a partnership, the power is shared among the partners. If the group is organized as a corporation, the power is vested in the hands of the stockholders. If the group is organized as a trust, the power is vested in the hands of the trustees.

Nowhere is the opinion of a shrewd French writer more justified that 'No great generalization is ever wholly true — not even this one.' " Few observers of group practice would subscribe without reservation either to the list of advantages cited below or to the list of disadvantages, the nature and ramifications of the subject are such, however, that few observers remain at dead center, balancing advantages and disadvantages evenly. It seems to be a subject on which most students take up a fairly well defined position, for or against, and draw on the rival arsenals of ideas listed below for their verbal ammunition.

The principal advantage claimed for group practice is that modern medicine is so complex that no one physician can comprehend ^{all} the niceties of diagnosis and treatment, that ~~as a result of this situation, most sick people~~ — if they are to get the best medical care — must be seen by more than one physician and that organization of physicians into groups is the only way in which this can be done efficiently and economically. It is claimed that physicians working together in a group are stimulated to keep up with medical progress more than physicians in individual practice and that each physician, constantly subjected to the informed appraisal of his fellows, has more incentive to do his best work and is less likely to develop slipshod habits of medical practice. The ease and value of consultations is enhanced because the consultant has the patient's whole medical record before him and can more quickly and efficiently bring his own special knowledge to bear on the case. Young physicians, especially those with specialist training, are enabled to concentrate from the beginning on the type of work in which they have been trained, avoiding not only the struggles of establishing a practice but also the loss of skill from disuse that is often the fate of the young specialist. On the

financial side a group of men, by pooling their resources, can maintain equipment for diagnosis and treatment that no one of them could maintain individually and can make efficient use of such expensive items as x-ray equipment. Physicians' incomes are more stable, and some claim that they are larger than incomes in individual practice. The physician in a group is freed from direct financial dealings with patients and is therefore able to do his best work medically without worry about whether he will be paid. He is enabled to take vacations and trips for postgraduate study without jeopardizing his practice or his future prospects. The patient benefits by less expensive service (the usual claim is that he gets more service for the same cost than he would get from an individual practitioner), as well as by the ready availability of competent consultation when he needs it. A well run group is alleged to raise the medical standards of the whole community, by exemplifying modern medical care. Groups have the facilities for, and tend to stress, preventive medicine. By providing nursing and secretarial help economically group organization enables the doctor to spend more of his time doing medical work and relieves him of work that can be done as well or better by less highly trained personnel. A final claim is that group practice facilitates the organization and efficient operation of prepayment plans.

Critics of group practice deny some of these advantages categorically but generally take the stand that the advantages are theoretical and that, although they may be true for a few groups, the great majority of groups not only fall far short of the theoretical ideal but also replace alleged advantages with actual faults. The most important criticisms are that most patients can be adequately treated by an individual practitioner with the equipment that any physician would have in his office and that it is inefficient, time consuming and unduly expensive to give every patient the questionable benefit of being treated by two or more physicians in offices fitted out with all the latest diagnostic and therapeutic equipment. This sort of treatment should be reserved for the approximately 15 per cent of patients who really need more than the general practitioner can give them. In addition, the physician in a group is deprived to some extent of independence of judgment and action, and his professional growth is stunted by constant supervision. A physician may get some stimulation from his intimate associations within a group, but he thereby cuts himself off from association with the larger number of physicians in his community, so that he actually suffers a net loss in this respect. The prospect of higher income in group practice is illusory and materializes only for the physician with poor training or personality who could not succeed in individual practice, the well trained physician can

make more in individual practice. (This claim, incidentally, is concurred in by many of the advocates of group practice, who contend that group practice is the best way to practice honest, satisfying medicine, but is not the way to make the most money.) The group's claim for ease of consultation and availability of laboratory service is conceded to be of value in medically undeveloped regions but is said to be of decreasing importance as a region develops specialists, hospitals and laboratories, which enable the practitioner who is not allied with a group to pick the best consultant or laboratory to care for the particular illness of the particular patient, whereas the group physician is limited in his referrals or laboratory work to the available specialists or equipment within the group. Mechanization of medicine, with undue dependence on a dragnet type of laboratory workup, and referral of patients without adequate medical reason are alleged. Allied to these are the allegations that in some groups every patient is "sent through the mill" of referrals and laboratory work, that "made work" is thrown to the less busy members, or that consultations are ordered with an eye on the fee rather than for any medical indication. The obvious advantages of concentration of equipment and the handling of finances by a business manager are often more than counterbalanced by the economic necessity of making the large investment in building and equipment pay its way and by the interjection of business persons untrained in medical ethics into the relations between patient and physician, with the result that unethical promotion and publicity policies often develop. The patient-doctor relation is further disrupted by the fact that a patient does not have "his doctor" who knows and understands him, but has a whole set of physicians, each of whom concerns himself with only a fraction of the patient's person. (Advocates of group practice are somewhat divided regarding the desirability of having a "personal physician" for each patient, but they all agree that such a relation can be maintained in group practice as easily as in individual practice.) The patient's choice of physician in individual practice is lost as soon as referral becomes necessary, since he is limited to the specialists within the group. Furthermore, many groups that set themselves up as giving complete specialist coverage actually have inadequately trained physicians posing as specialists. This is claimed to apply especially to groups having prepayment plans.

ANALYSIS OF CONTROVERSY

These controversial and contradictory sets of statements may be roughly divided into those having to do with medical care per se and those having to do with medical ethics. It will be noted that the former are by implication largely concerned with the practices of service groups. Reference group

receive tacit approval if their specialists are of reasonably adequate caliber and if they avoid unethical practices. The statements that seem to attack group practice as such apply principally to the practices of service groups and with double force to the service groups that have prepayment plans. On the other hand, some of the advantages claimed for group practice also apply to the larger groups with diversified well trained specialists rather than to the small service groups.

It may be said, then, that whereas the fundamental question in group practice concerns its ability to provide medical care, as compared with that afforded by individual practice, realistic consideration of this problem requires that it be broken into two parts—the provision of general medical care and the provision of specialist care. It is essential to determine the extent to which groups carry out each of these functions and to evaluate their success in each case. To what extent does a specific group act as (and replace) a general practitioner, and to what extent is it a specialist? What are the trends in a given group or set of groups—toward increasing reference work or toward a greater volume of general-medical-care work?

Analysis of the controversy from this point of view, and in the light of the preceding paragraphs, shows that the real differences of opinion about group practice center around three basic considerations: whether the great majority (80 to 90 per cent) of sick people suffer from illnesses that can be adequately treated by a well trained general practitioner without consultation, if so, whether it is not wasteful to set up a group organization, with specialists and laboratory equipment, to take care of these ordinary and easily treated illnesses, and whether the 10 to 20 per cent of patients who need specialist care will not receive better care if their physician is free to refer them to the best specialist (or reference group) available for their particular illness, than if he has to refer them to the specialist within his own group, even though better specialists are available outside the group.

Answers to these questions and to such related and subsidiary questions as the role and functions of the individual general practitioner in service groups involve some degree of interpretation and therefore will never be supplied by any simple accumulation of facts, until the questions can be discussed in terms of facts rather than theories and impressions, however, little progress toward their elucidation can be made.

PRESENT STUDY

Answers to these basic questions and evaluation of the claimed advantages and disadvantages of group practice must rest on a foundation of factual data that is now lacking. The present study is designed to develop methods by which some of the principal factors peculiar to group practice can be

studied, analyzed and correlated and to apply these methods to a sample of existing groups. An effort will be made to obtain statistical information concerning medical group practice as it is now carried on and to develop statistical indexes of adequacy and quality of medical care. There is at present no way of measuring either of these important components of medical care. They can only be estimated on a subjective basis after prolonged observation by a trained and experienced physician, who is unable to express in exact words all the intangible factors on which he bases his judgment and the relative significance of each. Such subtle and informed judgment cannot be replaced by any purely statistical analysis, but an effort will be made to arrive at indexes that afford a preliminary crude estimate of adequacy and quality. Wherever valid data are available, the kinds and amounts of medical services that groups are called on to furnish will be related to the kinds and amounts of services provided by individual practitioners, and an effort will be made to correlate these data with specific organizational and administrative practices that are peculiar to groups.

METHODS

The objectives set for the present study must be sought by a variety of approaches. Determination of the number, size and distribution of groups of various kinds is being attempted by a mail questionnaire. Lists of groups have been obtained through the co-operation of the American Medical Association, Medical Administration Service, Incorporated, and the National Association of Clinic Managers, but none of the available lists include up to date information about the size, type or even the existence of the groups listed. The questionnaire has been circulated to all the groups on these lists, requesting information that will permit their classification according to location, size, ownership or sponsorship, type of practice carried on and type of organization. An effort is also being made to obtain the names of groups that do not appear on the present lists, so that they too may be included in this survey. A questionnaire form (Table 1) has been sent to all groups of which listings were available in 1946. Analyses of the responses will be presented in future studies. Any group that has not received the form is invited to communicate with the author.

For the intensive studies of individual groups, forms have been worked out for obtaining detailed information concerning the personnel of the group, both professional and nonprofessional, its office and equipment facilities, its form of organization, the scope and variety of its medical services, its administrative practices, both medical and business, and its budget by broad categories. The incomes of group members are not included in the study, such a study would be valuable, but present social,

economic and psychologic patterns are such as to rule it out. All this factual information, as well as an opinion survey of members of groups concerning the advantages and disadvantages of group practice and the desirable administrative and professional practices of groups, is obtained by a visit of the study staff to the group being studied, during which

data regarding actual medical practices, including the kinds of illness that groups of various sizes and types are called on to treat, the kinds and amounts of medical services that the groups furnish, the extent to which intragroup consultation is used, the extent to which laboratory and other facilities are utilized and the continuity of care. Such data are

TABLE 1 *Questionnaire Sent to All Groups of Which Listings Were Available in 1946*

GROUP PRACTICE STUDY	
1	Name of group
2	Street address
3	City, postal zone state
4	Number of physicians practicing (a) exclusively with the group (do not include interns, residents or fellows) (b) part-time with the group
5	Number of dentists practicing (a) exclusively with the group (b) part-time with the group
6	Number of graduate nurses employed by group For out-patient or clinic work
7	Does the group have its own hospital? Yes.....No..... If yes, number of beds
8	Name of medical director, or surgeon in-chief etc (If none please so state)
9	Name of business manager (if none, please so state) Dr, Mr, Mrs, Miss
10	Which of the following statements best characterizes your group (a) Informal association of doctors using common facilities (office space laboratory X-ray, etc) to some extent, but not sharing medical responsibility for patients
	(b) Formal association of doctors using common facilities
	(1) Members share medical responsibility for patients Yes.....No
	(2) Form of organization
	(a) Partnership only
	(b) Partnership plus employed doctors
	If so, number of partners.....
	(c) Single owner plus employed doctors.....
	(d) All doctors employed by sponsoring organization
	(e) Other
11	Is your organization affiliated with or a part of some other organization (such as a medical school faculty voluntary hospital labor union, consumers cooperative, etc)? Yes.....No
	If yes name of organization
12	Medical services furnished
	(a) More than one(circle fields covered) Med Surg Ob Gyn, Ped Eye ENT, X-ray Dentistry
	Other fields (specify)
	(b) One specialty onlyName of specialty.....
13	Primary or principal activity of the group
	(a) Diagnosis only
	(b) Consultation or referred service
	(c) General medical care
14	Does the group itself (or its sponsoring organization) operate a prepayment plan? Yes.....No
15	If not, does the group have arrangements to take care of patients for another organization which operates a prepayment plan (medical society plan Blue Shield, cooperative association, etc)? Yes.....No
	If yes, name of other organization
16	Date of this report

interviews are carried out with most or all of the physicians, the business staff and the medical-records librarian. One member of the study staff is a physician who attempts a medical evaluation of the general tone of the group, the way in which patients are handled and the surgical and other techniques used.

In addition to the information obtained by these means, the present study is designed to assemble

of basic value in arriving at an estimate of the influence of group organization on medical care and of the desirability of specific practices. To accomplish this, a technic has been worked out for the statistical analysis of samples of the group's medical records. Records of 200 patients seen during a single recent week are selected at random. Each visit of these patients during the week is analyzed according to complaint, physical and laboratory

examination, diagnosis and treatment. In addition, 200 recent patients are followed for two weeks after the first visit, and in each case a summation of the complaint, examination, diagnosis and treatment is obtained. A third part of the record study consists of the analysis of records in 30 recent obstetric cases.

Both major portions of the study — the detailed interviews and the record analysis — need further application before any final conclusions can be drawn concerning their validity in throwing light on some of the controversial points, but the results of their use in five studies to date are encouraging. More detailed reports on the development and form of these study techniques, as well as a preliminary analysis of the findings in the first five studies, will be the subject of future papers.

VOLVULUS OF THE CECUM AND ASCENDING COLON*

EDWARD L. YOUNG, M.D.,† HARVEY R. MORRISON, M.D.,‡ AND WALTER E. WILSON, JR., M.D.§

BOSTON

IT IS the purpose of this paper to present 7 cases of volvulus of the cecum and ascending colon and to discuss the preoperative diagnosis of this condition, with emphasis on roentgenologic findings, and the proper surgical treatment.

The problem of volvulus of the cecum is not frequent, and yet one of us (E. L. Y.) has operated on 3 cases in the last four years. The incidence in North America is relatively low. At the Massachusetts General Hospital over a period of fifty-seven years it was 1.15 per cent (6 cases) in 520 cases of acute intestinal obstruction exclusive of those resulting from strangulated external hernia. At the Touro Infirmary, New Orleans, during a sixteen-year period, the incidence was 1.4 per cent (6 cases) in cases of obstruction.² It was 0.1 per cent (1 case) in 956 cases of intestinal obstruction from 1934 through 1943 at the Boston City Hospital, and 1.4 per cent (3 cases) in 218 cases at the Faulkner Hospital from 1936 to 1945 inclusive. In spite of this low incidence, it is important to review the subject because early diagnosis will inevitably lower the appalling mortality, which is 100 per cent in unoperated cases¹ and from 17 per cent to 50 per cent in operated cases.²

ETIOLOGY

In the etiology of volvulus of the cecum, acute and chronic types are recognized. Sweet¹ has designated the latter as "subacute, recurring" and states that in both types "there is always a congenital lack of fixation of the cecum with a point of attachment below which the bowel rotates." It will be remembered that in the embryo, during the third stage of intestinal rotation, a process of fusion takes place between the mesentery of the ascending colon and the posterior parietal peritoneum. This process is usually completed by the end of the fifth month, in some cases, however, fusion is incomplete, and the mesentery remains free enough to allow these structures a varying degree of mobility. In a study of anatomic dissections, the cecum in 11.2 per cent of cases was mobile enough to allow the development of volvulus, and reports in the literature suggest that 10 to 15 per cent are free enough to undergo torsion.³

With this embryologic fault as a basis, certain extraneous factors may be superimposed to produce twisting of the first part of the large bowel. Miller

and Clagett⁴ enumerate these as follows: violent peristalsis following heavy purgation or overeating, abdominal tumors, mesenteric cysts, fecaliths, foreign bodies, direct violence, and habitual constipation. To these may be added acute appendicitis, as evidenced by one of our patients (Case 3), and pregnancy, which may be regarded as a specialized type of abdominal tumor. Basden⁵ reported a case of cecal volvulus in a thirty-eight-week-pregnant woman who was thought to be in labor, and Sheldon⁶ reported a case in a post-partum patient with onset of symptoms twelve hours after a low forceps delivery.

DIAGNOSIS

Although the diagnosis of acute volvulus of the cecum is not usually made preoperatively, it is believed that by careful x-ray study and a thorough review of the history and physical findings, it can be arrived at more frequently. The history is one of acute intestinal obstruction, and the essential points are characteristic. About 50 per cent of patients give a history of previous attacks of colicky abdominal pain,⁷ as in Case 4 below. The onset is sudden, and the chief complaint is abdominal pain centered in the right lower quadrant. There is usually nausea and vomiting.

The abnormal physical findings, which are confined to the abdomen, consist of distention, generalized tenderness and spasm of the abdominal musculature. On auscultation, peristalsis is obstructive in character or absent in the late cases. The fact that some patients are able to move their bowels or expel flatus does not invalidate the diagnosis.

The laboratory findings are not remarkable. There is usually a moderate leukocytosis. It should be emphasized that a rising white-cell count with a marked shift to the left indicates strangulation of the bowel.

Roentgenologic Aspects

In the diagnosis of volvulus of the cecum, the roentgenologist should play an essential role. Despite its rarity, this condition should be included among the differential diagnostic possibilities whenever the scout films customarily taken in acute abdominal emergencies are surveyed. A correct preoperative diagnosis is not only of academic interest but also of great assistance to the surgeon in planning his approach and procedure.

The cardinal points to be remembered are the demonstration of a dilated cecum with variable lengths of dilated ascending colon and terminal

*Presented at the annual meeting of the New England Surgical Society, Worcester, October 5, 1946.

†Surgeon-in-chief, Faulkner Hospital.

‡Roentgenologist, Faulkner Hospital.

§Assistant in surgery, Boston University School of Medicine.

ileum depending on the type and extent of the congenital mesenteric attachment, an abnormal position of the dilated cecum, which is found in the left upper quadrant in over 90 per cent of cases, together with the absence of a normal appearing cecal outline in the right lower quadrant — previous films showing its normal position or mobilization are helpful but not always available, the demonstration, by barium-enema examination, that the dilated portion of large bowel is proximal to the point of obstruction of the barium column, no barium-outlined cecum being identified in the right lower quadrant, and, also by barium-enema examination, the observation of at least the initial twisting and torsion of the mucosal pattern outlined by barium, bowel wall and gas

DIFFERENTIAL DIAGNOSIS

Obstructing tumors The twisting mucosal pattern is typical of volvulus, not of tumor, and the abnormal position of the cecum should help in the differentiation. In one of the cases reported below (Case 5) these conditions co-existed.

Obstructing adhesions Again, the abnormal position of the cecum and the characteristic mucosal twisting should aid in the differential diagnosis. In one case reported below (Case 6) there were volvulus and adhesions.

Dilated obstructed stomach Confusion may arise from the position of the gas-filled cecum in the left upper quadrant, which shows a large fluid level in films made in the erect position. Some authors have solved this problem by intubating the stomach or outlining it with a swallow of barium and separating the cecum from the stomach by fluoroscopy or films, as in Case 7 reported below.

Redundancy of the colon In Case 6, due to a redundant bowel, the point of arrest of the barium column simulated a small, normally placed cecum low in the right lower quadrant. Further study of the films showed the early torsion of the mucosa in the volvulus and a dilated cecum in the left upper quadrant.

TREATMENT

The treatment of acute cecal volvulus is surgical, and it is obvious that the earlier these patients are subjected to surgery the better the results, for the longer the blood supply has been compromised the more radical the necessary surgery must be. The fact that numerous technical procedures have been recommended suggests that the results of surgery have not been too satisfactory in the past.

There are several points to be kept in mind concerning the management of acute volvulus. The volvulus must be reduced, the obstruction must be relieved, and one must attempt to prevent recurrence. The various methods of accomplishing these ends are as follows: detorsion and cecostomy, which result in fixation of the cecum to the anterior wall,

decompressing the bowel at the same time, detorsion and cecocolic plication and fixation, and detorsion and resection of the cecum and ascending colon. Simple untwisting of the volvulus is never permissible.

It should be pointed out that there is no one set of rules that supersedes surgical judgment. For example, to return a distended, thin-walled, malnourished cecum to its normal position after cecostomy is to invite trouble. The patient in a case reported in the literature died on the tenth day after this procedure, and autopsy demonstrated that the cecostomy was tight but that peritonitis had developed, apparently from the passage of contaminated material through a thin, distended bowel wall.²

The same conditions prevail regarding resection of the volvulus followed by primary ileotransverse colostomy. One case (Case 5) in this series and another recorded by Holman⁴ demonstrate the danger of this maneuver. Death occurred on the ninth and seventh postoperative days, respectively, and although no autopsies were performed, it may be inferred that failure of the primary suture of a distended, edematous bowel wall was the cause.

As pointed out below, the procedure of choice when there is the slightest question of the competency of the ascending colon is reduction of the volvulus, and resection of the cecum and ascending colon by the method of Mikulicz. Since most patients are extremely ill, careful attention must be given to their postoperative care to ensure proper fluid and electrolyte balance and adequate nutrition.

CASE REPORTS

CASE 1.* A 47-year-old woman was admitted to the hospital on January 19, 1936, with a chief complaint of abdominal pain of 6 hours' duration. She had been awakened from a sound sleep by the pain, which was sharp constant and generalized throughout the abdomen. Shortly after the onset of symptoms, she took a dose of Agarol and later had two normal bowel movements. The pain persisted and she was sent to the hospital. No mention of vomiting was made.

The past history was irrelevant. The patient a general health has been good.

There were no remarkable physical findings except in the abdomen, where a peculiar form of distention was noted. It was somewhat sausage shaped and extended from the left upper quadrant to the right lower quadrant. There was no spasm of the abdominal muscles. The point of maximum tenderness was in the right upper quadrant. Vaginal and rectal examinations were negative.

The blood pressure was 120/70.

Examination of the blood revealed a white-cell count of 16,000. The urine showed a trace of albumin, and the sediment contained 2 to 4 white cells and 3 to 5 red cells per high power field.

No preoperative x-ray films were taken.

When the abdomen was opened through a right para median incision there was an escape of cloudy fluid. Exploration revealed the cecum and the ascending colon to be rotated twice on the long axis in a clockwise direction. The cecum lay to the left of the midline above the umbilicus and was discolored. The mesentery measured 15 cm in length. After the volvulus had been reduced the bowel did

*Reported through the courtesy of Dr. Charles C. Ludd, of the Boston City Hospital.

not return to normal color, and accordingly a double barrel colostomy was done between the proximal end of the transverse colon and the terminal ileum, the cecum and ascending colon being removed. The immediate postoperative condition was fair.

Five days later a clamp was applied to crush the spur, and 43 days after the original operation, the colostomy was closed. There was a stormy postoperative course, during which the patient developed lobar pneumonia. She recovered, however,

Rectal examination was negative.

The blood pressure was 155/90.

Examination of the blood showed a white-cell count of 24,000 with slight shift to the left.

X-ray examination by Dr. Alexander Vance was reported as follows:

Plain films of the abdomen show a huge gas shadow under the left diaphragm extending across to the right of

FIGURE 1 Case 2

A barium enema demonstrates the point of torsion of the volvulus at the arrow. "S" is barium in the stomach. "C" is the fluid level in the dilated cecum, with gas above it extending into the left upper quadrant.

and was discharged well from the hospital 93 days after admission.

CASE 2* A 54-year-old man was admitted to the hospital on June 11, 1941, with a chief complaint of swelling and distress in the epigastrium of 3 weeks' duration. The symptoms had gradually increased during the week prior to admission. There was no nausea or vomiting. The bowels had moved daily until the 3rd week of symptoms.

The past history was irrelevant.

Physical examination was negative. The abdomen was markedly enlarged and tense, with distention most noticeable above the umbilicus. Peristalsis was normal in the lower third of the abdomen. An ovoid mass, 22 cm in diameter, was roughly outlined in the right upper abdomen. There was no abdominal tenderness.

*Reported through the courtesy of Drs. John Marshall, Walter Garrey, and Alexander Vance of the United States Naval Hospital, Chelsea, Massachusetts.

the midline. There are no other dilated loops of bowel. The area of the cecum is clear, and no small bowel is outlined by gas shadows. A swallow of barium given by mouth demonstrates the stomach to be posterior and displaced slightly by the extremely large gas-filled mass.

A barium enema was administered, and the barium flowed freely to the middle portion of the ascending colon, beyond which barium failed to pass. The tip of the obstructed area was pointed, suggesting volvulus (Fig. 1). The findings were those of a hugely dilated cecum, with volvulus, probably on the basis of incomplete rotation and a long mesentery.

The abdomen was opened through a right rectus incision, and a distended large bowel presented. This was decompressed with a needle puncture followed by purse-string suture. A volvulus of the cecum and right colon was then demonstrated. This was reduced, and a Mikulicz ileotrans-

verse colostomy was performed. The immediate postoperative condition was satisfactory.

The patient had a moderately stormy course, apparently owing to an attack of bronchopneumonia. He was well enough, however, to have the spur crushed 13 days after the original operation. The colostomy was closed 85 days after admission. The patient had an uneventful recovery and was discharged 105 days after admission.

CASE 3 A 14-year-old boy was admitted to the hospital on November 24, 1942, with the chief complaint of pain

Examination of the blood disclosed a white-cell count of 8100 with 87 per cent neutrophils. The urine was normal except for 4 to 6 white cells per high power field in the sediment.

No preoperative x-ray films were taken.

When the abdomen was opened through a right rectus muscle retracting incision the cecum and appendix could not be felt. Exploration revealed a balloon-like mass in the pelvis which was found to be a much dilated and congested cecum with the ileum entering the lateral side of the mass. The cecum and ascending colon were twisted $1\frac{1}{2}$

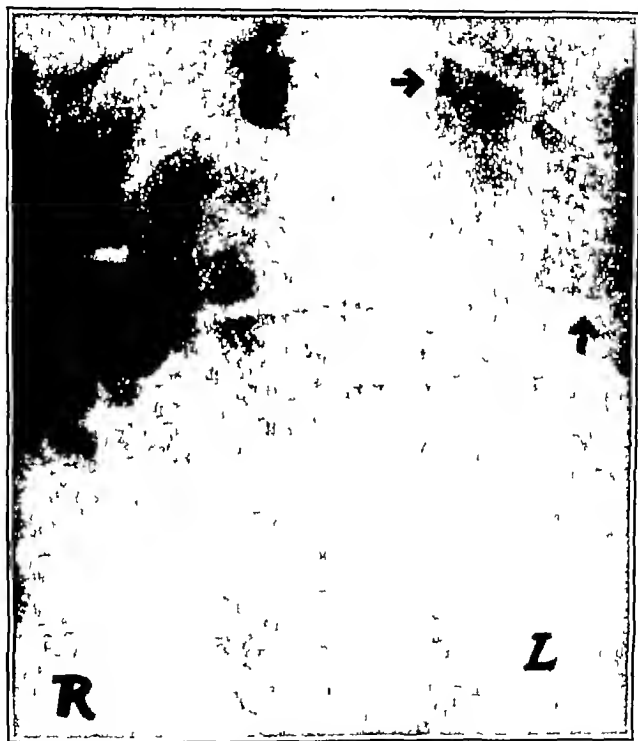

FIGURE 2 Case 4

This scout film demonstrates the dilated cecum in the left upper quadrant. It should be noted that the cecal shadow is absent in the right lower quadrant.

In the right lower quadrant of 4 hours duration. One week prior to admission he had experienced epigastric pain and nausea. The family physician started him on an ulcer regime but the symptoms persisted intermittently throughout the week. The patient vomited once during an attack. During this period the bowels did not move except on the day before admission following an enema.

The past history was irrelevant.

Physical examination was negative except for the abdomen. There was no distention but there was marked tenderness in the right lower quadrant with some increased muscle tone over the entire abdomen. On rectal examination there was marked tenderness in the right lower quadrant but no masses were felt. The blood pressure was 130/70.

times on the long axis and there was no mesentery to the first 15 cm of the large bowel. There was no evidence of gangrene and accordingly the volvulus was reduced and the appendix removed although it looked grossly normal. The cecum was emptied of gas, plicated and fixed in the iliac fossa.

The pathological diagnosis was acute appendicitis.

The patient made an uneventful recovery and was discharged 13 days after admission.

CASE 4 A 53-year-old man was admitted to the hospital on March 27, 1943, with a chief complaint of pain in the right upper quadrant of 24 hours duration. A renal calculus had been removed in June, 1942, and 5 weeks after discharge

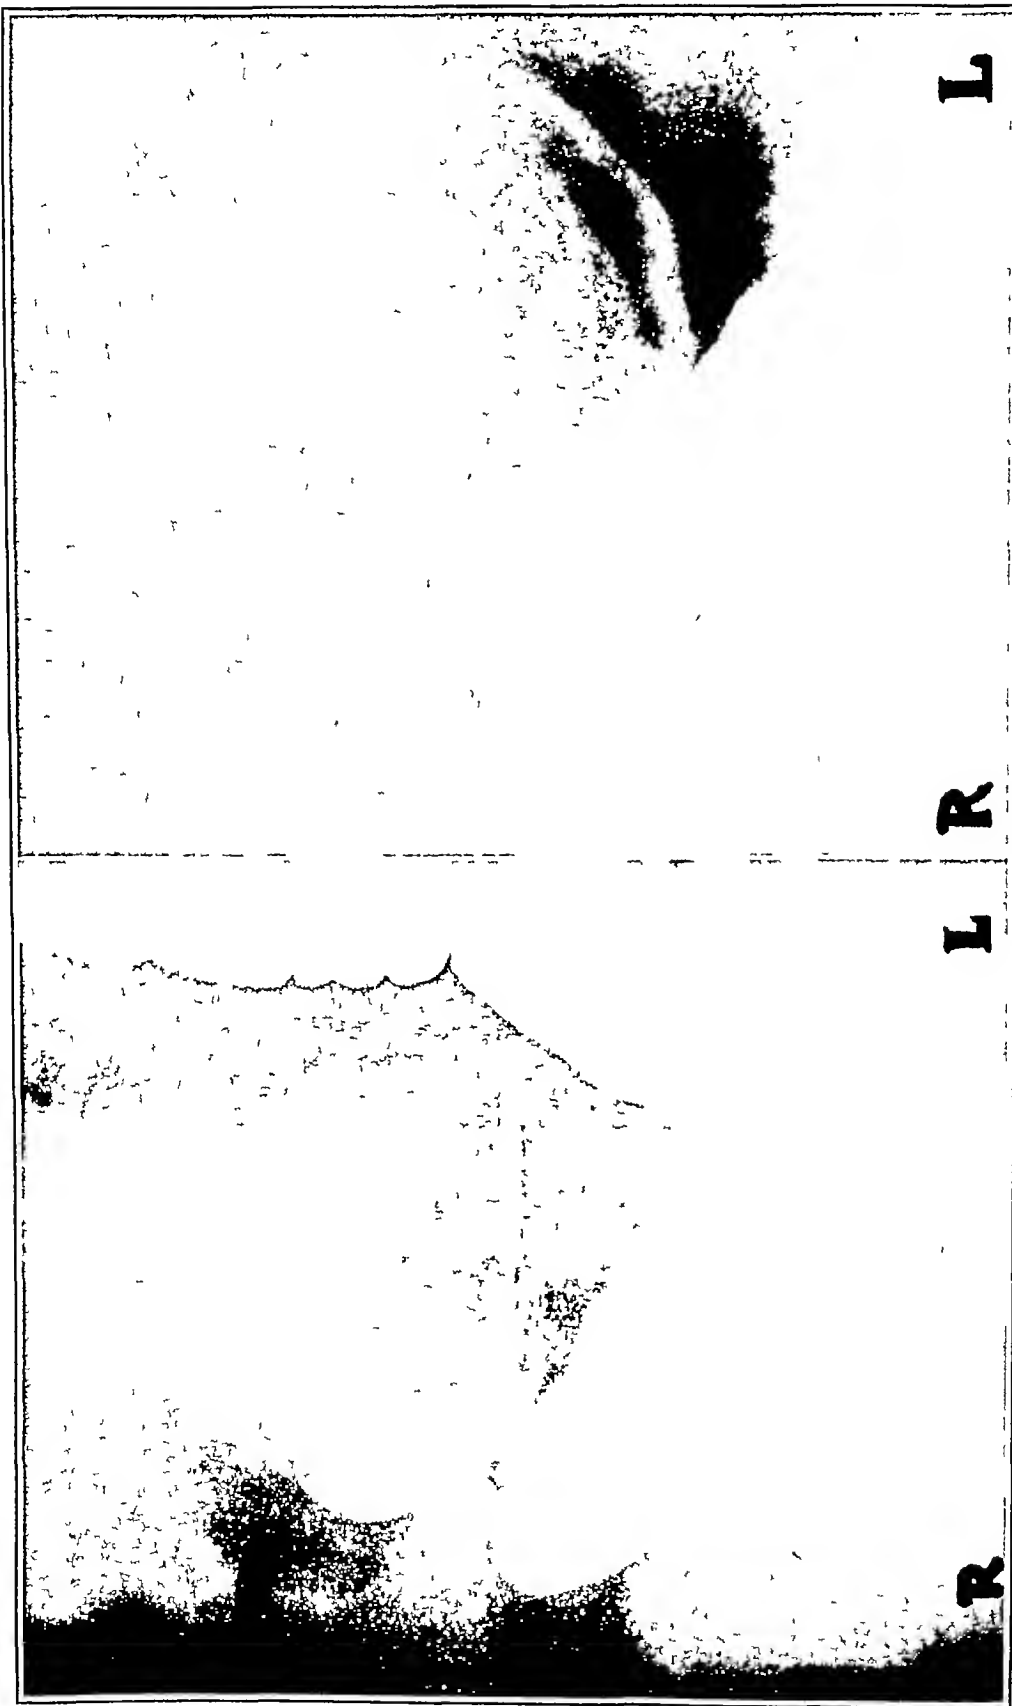

FIGURE 3 Case 4

A is a full barium-enema film demonstrating arrest of the barium column with torsion of the colon at that point. In B, a spot film, the site of torsion of the volvulus is outlined by barium, bowel wall and gas, with twisting of the mucosal relief.

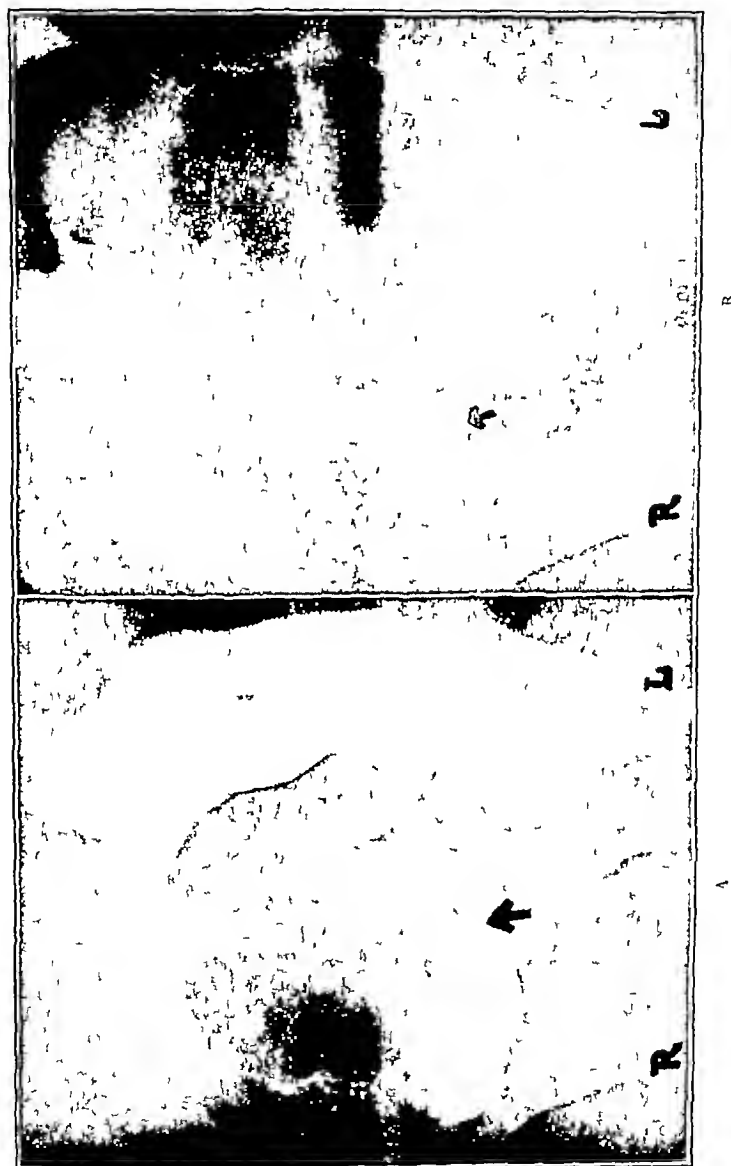

FIGURE 4 Case 6

A is a full barium-contrast film demonstrating the obstruction with filling of the volvulus outlined by a thin streak of barium above the arrow. Note the redundant colon and the point of barium arrest lying in the right lower quadrant and simulating the cecum. B is an evacuation film showing the torsion of the volvulus at the arrow. The dilated cecum is well seen in the left upper quadrant.

became disoriented and weakened and died on the 9th post-operative day. No autopsy was performed.

CASE 6 A 59-year-old woman was admitted to the hospital on November 24, 1945, with a chief complaint of nausea and vomiting of 5 days' duration. She had been constipated for 4 months. Four days before admission, she had become nauseated, but she had not vomited until 2 days later after a large meal that she had forced herself to eat. An enema at that time was returned clear, although the bowels had not moved for 2 days.

A pelvic laparotomy had been performed in 1910, and lysis of adhesions for intestinal obstruction in 1930.

Physical examination was negative except for the abdomen, which was distended throughout, with hyperperistalsis.

Examination of the blood disclosed a hemoglobin of 13.4 gm and a white-cell count of 16,600, with 70 per cent neutrophils. The urine was normal.

A previous barium-enema examination, done on September 26, 1930, had shown a normal position of the colon. A scout film of the abdomen 1 day after admission revealed dilatation of a loop of large bowel in the left upper quadrant, with numerous loops of dilated small bowel. At examination on the next day the barium column flowed freely through the colon, which had numerous redundant loops. The splenic flexure was above the gas-distended cecum in the left upper quadrant. Barium passed readily to the right iliac fossa, where the column met arrest. The point of torsion appeared to be pulled across toward the midline, and there was a twisting of the mucosal relief at the point of arrest typical of volvulus (Fig 4).

At operation numerous angulations of small bowel from adhesions were encountered. The cecum and ascending colon had rotated twice on its mesentery and had included loops of small bowel in the volvulus. The mass lay at the splenic flexure. Because of the marked redundancy a Mikulicz resection was done. The immediate postoperative condition was good.

On December 2 the patient showed signs of small-bowel obstruction. She was treated supportively with constant Wangenstein suction and parenteral therapy, without operative interference. The colostomy closed on January 9. Following this an abscess developed on the buttocks that was incised and drained. The patient was discharged well and with normal bowel function 67 days after admission.

CASE 7* A 70-year-old woman was admitted to the hospital on December 1, 1945, with the chief complaint of colicky pain in the abdomen of 2 days' duration. The pain subsided shortly after onset, but the night before admission it became severe and generalized throughout the abdomen. The patient had not expelled flatus or moved the bowels since the onset of symptoms. She had had two similar but milder episodes during the previous year.

A subtotal gastric resection had been performed in 1944 for an ulcer in the prepyloric region of the stomach.

Physical examination was essentially negative. The abdomen was distended, and there was generalized tenderness throughout. Peristalsis was hyperactive.

A barium-enema examination 1 year previously had shown incomplete rotation of the cecum. A scout film on admission demonstrated a dilated cecum in the left upper quadrant (Fig 5). The x-ray diagnosis by Dr Stanley Wilson was volvulus of the cecum.

At operation the dilated cecum was found in the left upper quadrant. The blood supply had not been compromised, and the volvulus was accordingly reduced and a cecostomy performed.

The patient made an uneventful recovery and was discharged from the hospital 22 days after admission.

SUMMARY

The incidence, etiology, diagnosis and treatment of volvulus of the cecum and ascending colon are discussed. It is emphasized that treatment is surgical and that if there is the slightest question of the

viability of the cecum, a Mikulicz resection and exteriorization should be done. Cecocolic fixation and plication with cecostomy may be employed when the bowel has not been damaged.

If cecal volvulus is included in the differential possibilities when scout films are taken in acute abdominal conditions, the preoperative diagnosis can be established roentgenologically. Confirmation is assured by barium-enema examination.

From the scout films, the abnormally placed and locally dilated portions of large bowel should be identified as cecum, particularly in view of an absent cecal outline in the right lower quadrant. The barium enema corroborates these observations and demonstrates the twisting and torsion of the mucosal pattern at the point of barium arrest, characteristic of volvulus.

Seven cases are reported. Although no statistical conclusions can be drawn from this series, some of the notable features are as follows: all but 1 of the patients were in the middle or elderly age groups, 2 patients had had more than one previous attack, 4 patients were able to expel flatus or move the bowels in spite of the volvulus, at operation the most frequent location of the cecum was the left upper quadrant, and the only death occurred in a case treated by resection and primary ileotransverse colostomy. This is in accord with similar cases reported in the literature.

CARCINOMA OF THE ISLETS OF LANGERHANS WITH HYPERINSULINISM*

Report of a Case

RAPHAEL SANCHEZ-UBEDA, M.D.,† AND EDWARD A. CARR, JR., M.D.‡

PROVIDENCE, RHODE ISLAND

THREE years after the isolation of insulin by Banting and Best¹ in 1921, Harris² formulated the concept of hyperinsulinism. In 1927 Wilder³ reported the first recognized case. Since then over 150 cases of benign insulin-producing tumor have been reported. Unequivocal cases of carcinoma of the islets of Langerhans are unusual, we have been able to collect 23 such cases from the literature.⁴⁻²³ In 16 of these, hypoglycemia was observed. The following case is believed to represent another example of carcinoma of the islets of Langerhans causing hypoglycemia.

H. S., a 40-year-old man, was sent to a hospital in July 1945, by his physician, who had found a mass in the right

upper quadrant. He had consumed large amounts of alcohol for the preceding month; he had noted urinary frequency.

Physical examination at that time showed a poorly developed undernourished man with a tender nodular liver whose edge was palpable four fingerbreadths below the right costal margin. There were no other significant findings. Roentgenograms of the entire gastrointestinal tract were normal. Three separate determinations of the fasting blood glucose gave values of 67, 72 and 89 mg per 100 cc. Other laboratory data are not available. The patient was discharged on September 26, with a diagnosis of possible portal cirrhosis or carcinoma of the liver.

Thereafter the patient, according to his wife, continued to suffer abdominal pain and complained of feeling constantly weak and tired. His wife, who was with him most of the time, never noted any cold sweats, episodes of severe hunger, sudden mental changes, diplopia, sudden tremors, twitchings,

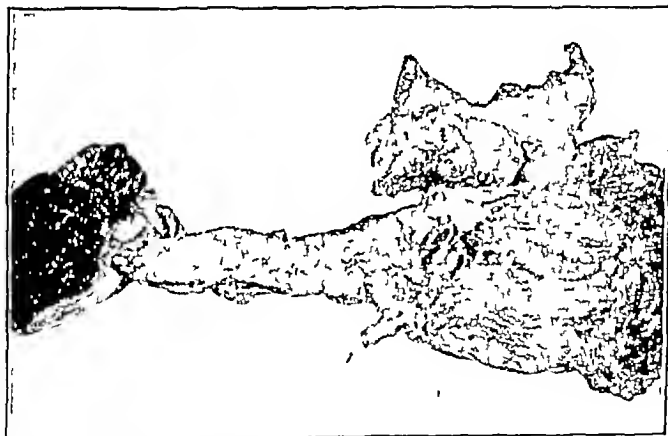

FIGURE 1 Longitudinal Section of Pancreas and Adjacent Organs

The primary tumor site can be made out in the tail of the pancreas. To the right a portion of the gastric wall is seen in relation to a large mass of tumor tissue.

upper quadrant. At that time the patient gave a history of a weight loss of 27 pounds in 2 months. For 6 weeks before admission epigastric pain, beginning about 1 hour before and ending approximately 2 hours after meals, had troubled the patient, but except for a 2-day period of vomiting and diarrhea 3 or 4 weeks before admission he denied other gastrointestinal symptoms. Amphojel and mineral oil had relieved the pain somewhat. He admitted that he habitually

somnolence or loss of consciousness. He seemed despondent however much of the time.

On October 20 the patient was admitted to this hospital in deep coma. He had apparently lapsed into coma while alone for a few hours at home.

Physical examination showed an emaciated man with sparse axillary and pubic hair. The skin was cold and moist and there was an early decubitus ulcer over the sacrum. The liver whose edge was blunt and extended four or five fingerbreadths below the right costal margin was hard; most examiners believed that definite nodules could be made out. A firm epigastric mass was palpated; this might have

*From the Department of Medicine and the Department of Pathology, Rhode Island Hospital.

†Formerly resident in pathology, Rhode Island Hospital.

‡Formerly intern, Rhode Island Hospital.

been a large nodule in the liver or a separate mass. The rest of the examination was not remarkable.

The temperature was 98.2°F by rectum, the respirations 20 and deep, and the pulse 100 and regular. The blood pressure was 150/90.

The blood glucose was 11 mg per 100 cc and the blood urea 10 mg per 100 cc. Later, examination of the blood revealed a red-cell count of 3,510,000, with a hemoglobin of 10 gm per 100 cc and a blood cholesterol of 104 mg per 100 cc, a blood Hinton test was negative.

About 100 cc of watery fluid was aspirated from the stomach, and 50 cc of 50 per cent glucose was administered

urinary output, which had been over 2800 cc in the first 24 hours, began to decrease sharply.

Thirty-four hours after admission the temperature rose to 102°F by rectum, and the respirations increased to 36 per minute. There were medium moist rales and bronchial breath sounds in the left lung anteriorly and at the left base. The white-cell count was 21,000, 30,000 units of penicillin was given intramuscularly at that time, followed by 20,000 units every 2 hours. During the next 8 hours the patient became virtually anuric. The blood pressure, which had varied between 100/60 and 150/80, fell to 66/60, and the skin became cold and moist. Thirty-eight hours after admission

FIGURE 2 Section of the Liver, Showing Massive Metastases.

intravenously, within less than 1 minute the patient recovered consciousness completely and was able to converse rationally, although he could not remember what had happened to him. Since vomiting followed every attempt to give food by mouth, further glucose was administered, most of it intravenously and the rest subcutaneously. Crude liver extract and supplementary vitamins were also injected parenterally. Several urine specimens showed a positive Benedict's test, which never exceeded a green reaction. Acetonuria was never present.

It was the opinion of both the Medical and Surgical services that the hypoglycemia was most probably due to an islet-cell tumor, and an additional diagnosis of portal cirrhosis was made. Opinion was divided regarding whether there were metastatic nodules in the liver, but it was agreed that the patient should be given the benefit of the doubt and explored in the hope that the tumor might be benign. The use of alloxan was suggested in the event that surgical treatment should prove impossible.

The patient's condition would not tolerate surgery at that time, however. To the general picture of cachexia there was added abdominal distention, with epigastric spasm on occasions, severe abdominal pain necessitated opiates. The

blood urea nitrogen was 7 mg., and the sodium chloride 436 mg per 100 cc.

Plasma was administered intravenously. The blood pressure rose thereafter but did not go above 90/60 during the rest of the hospital course despite further plasma. Moderate cyanosis developed, oxygen was given by Burgess box.

Although the patient's inability to go without nourishment long enough to reach an adequate fasting blood sugar level made a standard glucose-tolerance test inadvisable, the rapidity with which glucose disappeared from the blood with little concomitant glycosuria pointed emphatically to hyperinsulinism. To show this to greater advantage the patient was given 210 gm of glucose intravenously (in 5 per cent and 15 per cent solutions) from the 42nd to the 50th hour after admission. During that time 500 cc of a 5 per cent glucose solution was also injected subcutaneously. All glucose intake was then discontinued abruptly. The blood sugar was 43, 23 and 24 mg per 100 cc, respectively, 30, 60 and 90 minutes later. By that time the neurologic signs precluded further starvation, 50 cc of 50 per cent glucose administered intravenously temporarily restored the blood sugar.

Since it did not seem possible that the patient would improve sufficiently to permit surgical intervention, arrange-

ments to procure alloxan were made with the Department of Biology of Brown University. Alloxan administration was to be started on the following day.

Abdominal pain continued to be severe, and the patient vomited frequently. The urine output was only 1 or 2 cc per hour. The urine contained many red and white cells and granular casts. There was never more than a trace of sugar present. The temperature ranged between 100 and 102°F.

While glucose and physiologic saline solutions were given parenterally, an attempt was made to stabilize the blood glucose by furnishing protein. The patient received a 5 per cent solution of amino acids along with part of the parenteral glucose, 50 gm of protein was given in this way. A total of 1000 cc of plasma was administered during the patient's stay in the hospital. From the 53rd to the 65th hour after admission while parenteral glucose, sodium chloride and protein were given as noted above whole adrenocortical extract (Eschatin) was given subcutaneously. The blood glucose preceding the first dose was 155 mg per 100 cc. Four hours after the administration of 10 cc, the blood glucose was 189 mg per 100 cc. A second dose of 5 cc was administered and 1 hour later the blood glucose was 173 mg per 100 cc. Two more 5-cc. doses were given 8 and 12 hours after the initial dose. The blood glucose after the latter dose was 180 mg per 100 cc. At that time the blood sodium chloride

tingly with the normal pancreas infiltrating in the form of thin bands and blunt projections. The head and body of the pancreas were normal. In the region of the gastrophilic ligament there was a roughly spherical mass (10 by 6 by 8 cm) of whitish-gray tissue with frequent, soft, pinkish gray areas. The peritoneum in this area was studded with friable nodules of similar tissue that merged with the main mass and enlarged lymph nodes which were also involved. The liver weighed 3500 gm., its surface was extensively mottled by areas of pinkish-gray tissue. On section this tissue was

FIGURE 3 Section of the Primary Tumor in the Pancreas

FIGURE 4 Section of the Metastatic Tumor in the Liver

found to have supplanted a large portion of the liver parenchyma. The right lobe was almost totally replaced by tumor tissue and the left lobe was involved to a lesser degree. All in all approximately 34 of the liver had been supplanted by tumor (Fig 2). The adrenal glands, kidneys and bladder were normal.

The tumor in the pancreas was composed of oval or polyhedral cells. The cytoplasm was slightly acidophilic and fairly abundant. The nuclei were well stained round and centrally placed in the cells, which were quite uniform in size and shape. Infrequent mitoses were noted. The cells were arranged in solid groups in the form of short anastomosing cords and rounded collections which at times attained considerable size. Occasionally these collections of cells were lined by a clear space and were in intimate contact with fine-walled capillaries. It was difficult to distinguish these structures from normal islets. At other points the cells were gathered in smaller round groups, separated from each other by thin strands of connective tissue with abundant capillaries (Fig 3). They tended to be larger than the usual islets of Langerhans. In no area did the tumor simulate acinus or duct formation. Throughout the tumor large areas of necrosis and hyalinization were noted. Thick connective-tissue trabeculations crossed through the neoplasm, separating the tumor into irregular nodules. No evidence of capsulation was present, and neoplastic cells were seen invading the normal pancreas irregularly. The noninvolved portions of the pancreas presented a normal pattern; the islets were not remarkable. In the liver (Fig 4) and lymph nodes the tumor adopted essentially the same structure and cytology. Small nodules of tumor tissue were well preserved, otherwise there was considerable necrosis. The liver-cell cords were well preserved. In the neighborhood of metastases however, there was some vacuolization of cells and disintegration. Efforts to stain the tumor specifically with Mallory's modified Azan stain and the Gomori's phloxine stain gave negative results.

We are indebted to Dr. George Gomori, who of the tissue

was 404 mg, the urea nitrogen 30 mg, and the creatinine 4.3 mg per 100 cc. The white-cell count was 14,500 with 50 per cent mature and 33 per cent young neutrophils, 11 per cent myelocytes, 4 per cent lymphocytes and 2 per cent monocytes.

Following this the patient received intravenous physiologic saline solution and plasma the dosage schedule of adrenocortical extract continuing as before. No improvement occurred and the patient expired 72 hours after admission. In a blood specimen taken 2 hours post mortem the sodium chloride was 476 mg., and the glucose 110 mg per 100 cc., and the icteric index was reported as less than 6 units.

The total carbohydrate intake was 1680 gm., the total protein intake 110 gm., and the total sodium chloride intake approximately 32 gm.—excluding the small amount of nonishment that the patient was able to take by mouth.

Autopsy. Post mortem examination was performed 2 hours after death, permission being restricted to the abdomen. Positive findings included the distal 6 cm. of the tail of the pancreas, which was occupied by an elevated grayish white, firm tissue. The surface was moderately lobulated and smooth. The tip of the pancreas was adherent to the hilum of the spleen and the capsule of the spleen had been infiltrated superficially (Fig 1). On section this tissue blended indis-

The kidneys showed congestion throughout. Minute vacuoles were noted in the cells of the proximal convoluted tubules. Rare casts were seen. Otherwise, there was nothing abnormal. Sections stained for glycogen degeneration revealed no abnormality.

Multiple sections through the adrenal glands demonstrated abundant normal adrenal tissue.

After preservation in the icebox for 17 hours, approximately 25 gm of tissue taken from many portions of the liver metastases was extracted according to the method of Best, Jephcott and Scott.²⁷ A rabbit weighing 2 kilograms

any surgical procedure doubtful, the best interests of the patient demanded that he receive the benefit of exploration, provided that his condition could be sufficiently improved to tolerate the operation. It is unfortunate that alloxan was not immediately available. The experience of Brunschwig et al.^{24, 25} in a case of hyperinsulinism due to malignant islet-cell tumor suggests that the use of alloxan is of

received an injection of 1 cc containing the extract of approximately 4 gm of this tissue. The blood sugar values at 0, 30, 75 and 120 minutes after injection were respectively 85, 170, 140 and 85 mg per 100 cc. In the control experiment a rabbit weighing 3 kilograms received an injection of 1 cc containing a similarly prepared extract of approximately 5 gm of normal liver tissue. The blood sugar values at 0, 30, 60 and 120 minutes after injection were, respectively, 75, 75, 70 and 75 mg per 100 cc. No control extract of normal pancreatic tissue was made. It was concluded that no insulin was present in the extracted metastatic tumor tissue.

The salient features of 23 previously reported cases of well established islet-cell carcinoma are presented in Table 1. Cases of reported cancer, without metastases, in which the diagnosis was mainly based on the partial absence of the capsule and pathologic variations suggesting malignancy were not included.

The hospital course in the case reported above was hectic and not conducive to elaborate studies. All efforts were directed toward the prevention of a hypoglycemic death and the preparation of the patient for exploration. Although it was the opinion of the majority of the staff that the hypoglycemia was due to a malignant islet-cell tumor, the suspicious findings in the liver making the outcome of

definite value in the symptomatic treatment of such patients.

In retrospect, certain deductions regarding the cause of the hypoglycemia may be made. Given a case of pancreatic carcinoma demonstrated at autopsy and with three fourths of the liver destroyed by metastases, one is not tempted to invoke other bases for the hypoglycemia. The history of weight loss, asthenia and gastrointestinal symptoms in a patient with sparse axillary and pubic hair, as well as a low concentration of glucose and sodium chloride in the blood, brings up the question of adrenocortical insufficiency, but the autopsy findings did not support such a diagnosis.

Liver dysfunction as the basis of the hypoglycemia merits stronger consideration. Several cases of severe and at times fatal hypoglycemia, for which no explanation was found other than marked histologic liver damage, have been described.^{7, 28-31} In the case presented above the liver was seriously involved by metastases, but the ability to excrete bilirubin was unimpaired. Although hepatogenic hypoglycemia is suggested by certain negative considerations, — namely, that insulin was not demon-

strated in the metastases and that beta granules were not demonstrable in the neoplastic cells, — a more plausible explanation is available.

The gross and, especially, the histologic characteristics of this pancreatic tumor make its islet-cell origin almost incontestable. The extraordinarily rapid consumption of injected glucose was most impressive. Together, these findings render the diagnosis of carcinoma of the islets of Langerhans with hyperinsulinism difficult to avoid.

Extraction of insulin from the metastases would have given the most conclusive proof possible that the tumor was insulin-producing. It is unfortunate that we relied solely on this tissue, much of which may have been necrotic, to the exclusion of the primary site. No conclusion can be drawn from the failure to demonstrate beta granules in the tumor cells. Attempts by various investigators to demonstrate specific granulations in neoplastic islet tissue have in most cases been inconclusive in view of the present meager knowledge of the staining properties of neoplastic tissue.²²

The glucose-tolerance test is usually considered to follow characteristically different forms in hyperinsulinism and hepatogenic hypoglycemia.²³ Fraser, Albright and Smith,²⁴ however, found the glucose-tolerance test to be unreliable in hyperinsulinism. A study of the test in 11 of the previously reported cases of islet-cell carcinoma with hyperinsulinism failed to show a constant pattern, although a rapid fall to hypoglycemic levels occurred in 8 cases. One cannot make an unequivocal diagnosis of hyperinsulinism on the basis of a glucose-tolerance test, extremely rapid disappearance of the glucose from the blood without appreciable initial hyperglycemia remains, however, strongly suggestive of hyperinsulinism.

The use of adrenocortical extract should be briefly noted. The presence of certain features suggestive of Addison's disease and, especially, the need for a more stable supply of glucose made it desirable to supplement the glucose intake with protein and adrenocortical extract. Following these measures the blood sugar rose, but no conclusions can be drawn because of the agonal state at that point.

SUMMARY

A case of severe hypoglycemia, shown at autopsy to have carcinoma of the islets of Langerhans with metastases to the liver, is presented. The possible bases for the hypoglycemia are considered, and it is concluded that the patient suffered from hyperinsulinism.

The principal features of 23 previously reported cases of carcinoma of the islets of Langerhans are discussed.

MEDICAL PROGRESS

ENDOSCOPY*

EDWARD B. BENEDICT, M.D.†

BOSTON

LITERATURE directly or indirectly related to endoscopy continues to accumulate with amazing rapidity. Each year seems to bring forth additional indications for endoscopic procedures and a wider recognition of their usefulness to the medical profession.

ANESTHESIA

According to Clerf¹ the endoscopist employs all types of anesthesia and all methods of induction. It is not always easy to make an endoscopic examination of the air and food passages under local anesthesia, and the casual endoscopist frequently chooses general anesthesia. Routine methods following fixed rules do not make for good anesthesia. As a preanesthetic agent, morphine is valuable whether the anesthesia is to be of local or general type. The barbiturates are also widely used as preanesthetic agents. It is often hazardous to employ local anesthesia in endoscopic procedures in children.

BRONCHOSCOPY

Anatomy Brock² has written an excellent book on the anatomy of the bronchial tree, with special reference to the surgery of lung abscess. This book considers bronchial embolism and posture in relation to lung abscess, as well as the level of the interlobar fissures of the lungs, and then describes the anatomy of each lobe individually. It is well illustrated with photographs, diagrams and roentgenograms. In addition, there are illustrations of bronchoscopic views, as well as diagrams illustrating surface markings and map diagrams of the bronchopulmonary segments.

Atelectasis An unusual cause of atelectasis—namely, epistaxis with aspiration of blood—has been reported by Kartagener.³ This is believed to be the first case of the kind described in the literature.

Bronchiectasis Jones, Peck and Willis⁴ state that tuberculosis in children is frequently complicated by tracheobronchial tuberculosis. Such bronchial lesions are frequently associated with obstructive pneumonitis. Bronchiectasis, as shown by a bronchogram, was present in 24 out of 34 children, or 70 per cent. The authors consider pulmonary tuberculosis in children to be a common cause of bronchiectasis. Symptoms of bronchiectasis, however, were not

marked, and pneumonectomy was advised in only 1 case.

Olsen⁵ believes that bronchoscopy should be performed at least once in every case of bronchiectasis. Bronchial obstructions, such as those resulting from foreign bodies, tumors, broncholiths and bronchostenosis, may be discovered. The relief of any bronchial obstruction will be helpful. In some cases repeated bronchoscopic aspirations may be beneficial.

Foreign body Richardson⁶ calls attention to certain pitfalls in the diagnosis and removal of foreign bodies in the respiratory tract. One of the sins of omission is that the physician not only forgets to ask about the possibility of a foreign body but also fails to believe the patient's own story. Fluoroscopy or inspiration and expiration films, or both, are important, especially when a nonradiopaque foreign body is suspected. Unless a foreign body can be completely visualized, it is dangerous to attempt its extraction.

Adenoma In a report of 7 cases of bronchial adenoma, Nager⁷ states that only 2 patients were over forty years of age at the time of the onset of symptoms. The beginning of the tumor may be associated with the end of puberty. Asthmatoïd wheezing and hemoptysis are often the first signs, with bronchial stenosis, atelectasis and pulmonary suppuration following. Bronchoscopy is essential for early diagnosis. Surgical methods of treatment are indicated for tumor within the deeper layers. Hemorrhage associated with sudden cessation of respiration and death resulted in 2 cases from electrocoagulation.

Von Albertini⁸ has studied 10 cases of bronchial adenoma from a pathological standpoint. He believes that there is a close relation between bronchial adenoma and bronchial carcinoma because histologically both seemed to be derived from bronchial epithelium.

Moersch⁹ states that adenoma occurs approximately one tenth as frequently as carcinoma of the bronchus. It tends to occur in younger patients than carcinoma does. The average age of patients with bronchial adenoma was thirty-seven years as compared to an average age of fifty-four years in those with bronchogenic carcinoma. Adenoma occurs more frequently in the female than in the male, whereas the reverse is true of bronchogenic carcinoma. The average duration of symptoms before diagnosis of adenoma of the bronchus was

*From the Massachusetts General Hospital.

†Instructor in surgery, Harvard Medical School, endoscopist, Massachusetts General Hospital.

twenty-six months in his series, whereas the average duration before the diagnosis of carcinoma was eight months. Furthermore, the average life expectancy of patients with bronchogenic carcinoma was, in his experience, only fifteen months after onset of symptoms, and that in cases of adenoma is much longer. Probably the most valuable single aid in the differential diagnosis of bronchial adenoma is bronchoscopy in the course of which tissue can be obtained for positive microscopic diagnosis.

Tinney¹⁰ has found that opinions differ concerning the most satisfactory method of treating bronchial adenoma. In general, the decision rests between endoscopic removal and extirpation of the lesion by means of lobectomy or pneumonectomy. Conservative treatment is recommended if the adenoma is attached to the bronchial wall by a narrow pedicle, is movable and is situated in a bronchus that can be adequately and thoroughly visualized bronchoscopically. When the adenoma is situated so close to the carina that the usual operative measures are impossible, removal of the tumor with the bronchoscope is indicated. Bronchoscopic treatment is indicated when the general condition of the patient is such that lobectomy or pneumonectomy is unduly hazardous. Patients who have been treated by this method should undergo bronchoscopic examination at least once a year so that any recurrence of the adenoma may be found early. If the tumor that has been treated bronchoscopically tends to recur, it is not advisable to continue the bronchoscopic treatment. The advantage of removal of the tumor by means of lobectomy or pneumonectomy is that after the lesion has been removed by this method recurrences are rare, whereas recurrences are comparatively frequent after removal through a bronchoscope.

McDonald,¹¹ in a discussion of the pathologic aspects of adenoma, believes that there is a tendency for adenoma of the bronchus to infiltrate the bronchial wall and the peribronchial tissues. In 13 of the 15 cases in which the lung was available for study, such invasion had occurred. In the remaining 2 cases there was no infiltration of the neoplasm into the bronchial wall peripheral to the bronchial cartilage, the main mass of tumor being within the lumen of the bronchus. Adenomas invariably arise from main-stem or large bronchi. The condition of the lung distal to the neoplasm depends on the degree of bronchial obstruction that the tumor produces. No metastatic growths were found outside the thorax in 2 cases of adenoma of the bronchus in which necropsy was performed. In only 1 of the 38 cases was a local hilar lymph node involved, and that node was adjacent to the neoplasm.

Clagett¹² believes that the most satisfactory treatment of adenomas can be achieved by the co-operative efforts of the bronchoscopist and the thoracic surgeon. Bronchoscopy must always be

performed at least once and often several times to obtain specimens for accurate pathological diagnosis and to remove at least enough of the growth to relieve the obstruction of the bronchus so that the atelectatic lung can become aerated and any infection distal to the tumor can be drained effectively. In cases in which all or nearly all the visible tumor can be removed bronchoscopically and in which there is no serious damage to the lung distal to the growth, particularly if the patient's general physical condition contraindicates thoracotomy and pulmonary resection, there is no serious objection to this method of treatment. The patient who is treated by bronchoscopic removal of the tumor must be prepared to accept repeated bronchoscopic examination, however, since the tumor sometimes recurs and removal may be required every few months or years. The bronchoscopic treatment is not without risks and difficulties. These tumors are vascular, and serious hemorrhage is occasionally encountered. Since the risk of pulmonary resection has been reduced so greatly in recent years, Clagett believes that the great majority of bronchial adenomas are best treated by pulmonary resection. These are growing tumors, whether or not they are malignant. Often, the portion of tumor outside the bronchus is larger than the intraluminal portion so that only a small part of the tumor can be removed bronchoscopically. In many cases, by the time the tumors cause symptoms that cause the patient to seek diagnosis, the lung distal to the adenoma has already been seriously damaged. The lung is atelectatic and infected, extensive bronchiectasis or fibrosis is frequently present. Pulmonary abscess, empyema and brain abscess are not rare complications. Resection has the advantage that it can be carried out in one stage, and further examinations and treatment are not necessary. Unless the situation of the adenoma makes pneumonectomy necessary, lobectomy is adequate, since the slow-growing, benign nature of these growths makes extensive resection of the lung unnecessary. The age group in which adenomas are found makes the patients particularly good candidates for resection since they tolerate the operation well. With the modern technique for pulmonary resection the operation can be carried out with a risk of only about 5 per cent.

Lipoma. Watts, Clagett and McDonald¹³ have discussed bronchial neoplasms that, although histologically benign, may, through occlusion of a bronchus, give rise to atelectasis and often fatal suppuration in the tissue of the lung distal to the occlusion. The authors considered particularly a case of lipoma of the bronchus and stated that fat is a normal component of the bronchial wall. Fat is often present in the smaller bronchi until they reach the diameter of 1 mm. Fat may also be found in adenomas. In fact, fat occurs in association with other tumors far more frequently than it occurs alone. In the case reported a diagnosis of pulmonary

tuberculosis was made from the roentgenograms of the thorax, but tubercle bacilli were not found in the sputum. At bronchoscopic examination, a thick purulent secretion was observed in both main bronchi but no obstructing lesion could be seen. Because the lesion seemed to be confined to the upper lobe of the left lung, it was decided to perform exploratory thoracotomy. The upper lobe was atelectatic and was removed. Examination of the removed lobe by the surgical pathologist revealed a soft, gray, pedunculated tumor, 2 cm in diameter, in the main bronchus of the upper lobe of the lung, it was attached to the wall by a narrow pedicle, completely occluding the lumen. Microscopically, the entire tumor consisted of lobules of mature fat cells supported by a delicate fibrous stroma.

Carcinoma Guerra, Rousseau, Daumy, Amat and Aguirre Medrano¹⁴ report 4 cases of carcinoma of the trachea. They believe that there is a low incidence in the trachea, especially as compared to carcinoma of the larynx. About half the tracheal tumors occur in the lower third.

In a study of primary lung tumors Adams¹⁵ reported that 54 per cent of the group were epidermoid carcinomas, 13 per cent were adenocarcinomas, 4 per cent were oat-cell carcinomas, and 11 per cent were undifferentiated, 18 per cent could not be classified. Bronchoscopy was positive in 72 of 84 cases of epidermoid carcinoma (86 per cent), negative in 3 cases and not done in 9. Clinically, epidermoid carcinoma of the lung tends to have a slower course than other types of carcinoma. The propensity of adenocarcinomas toward cerebral metastasis is striking. The outlook for arrest of disease by resection is best in the epidermoid group, becoming progressively unfavorable throughout the other groups.

According to Wandall,¹⁶ the demonstration of tumor cells in the sputum allows definite establishment of the diagnosis of carcinoma in about four fifths of cases of primary pulmonary cancer. The specimen must be from the bronchi and must not be allowed to stand for more than eight hours. By the use of bronchoscopic biopsy and by examination of the sputum, the diagnosis of carcinoma of the lung can be verified in about 90 per cent of cases. Sometimes, exploratory thoracotomy may be necessary.

Herbut and Clerf¹⁷ have also made a cytologic study of bronchoscopically removed secretions in bronchogenic carcinoma. In 30 consecutive cases bronchial secretions were stained by the Papanicolaou technic. Cancer cells were demonstrated in 22 cases, or 73 per cent. In the same series a positive morphologic diagnosis from a study of tissue removed endoscopically was obtained in 11 cases, or 36 per cent. Cancer cells were present in the secretions in 7 cases in which bronchoscopy was negative. Sputums were examined in 5 cases in

which cancer cells were present in bronchial secretions, and in only 1 of these were neoplastic cells found. The authors, therefore, consider examination of bronchial secretions for tumor cells superior to examination of sputum. The method is presented not as a substitute for but as an adjunct to the means already employed in the diagnosis of pulmonary carcinoma. It is particularly useful in cases in which the tumor is located at the periphery of the lung or in the upper lobe.

Sarcoma Cote¹⁸ reports the case of a sixty-six-year-old woman with pulmonary sarcoma in whom the diagnosis was made only after three bronchoscopies. The left lung was collapsed, and after the first bronchoscopy it became aerated with improvement in the patient's condition, microscopical study of the biopsy, however, did not give a positive diagnosis. A month later the symptoms recurred and bronchoscopy was performed a second time, but again the pathologist could not make a positive diagnosis. Six weeks later, bronchoscopic biopsy showed fibrosarcoma. The patient died within six months of the first bronchoscopy, and autopsy revealed a fibrosarcoma completely occluding the left main bronchus and partially occluding the right main bronchus. No metastases were demonstrated.

Tuberculosis Janes¹⁹ has written editorially regarding lobectomy and pneumonectomy in the treatment of pulmonary tuberculosis, stating that patients with well marked bronchial stenosis should be submitted to lobectomy or pneumonectomy provided the disease in the remainder of the lung is sufficiently healed or quiescent. The operation should not be undertaken if it will necessitate the division of the bronchus through a site of active disease.

Sweet²⁰ reported 27 cases of lobectomy and 36 cases of pneumonectomy in pulmonary tuberculosis. Bronchoscopy was used freely as a diagnostic measure whenever bronchial disease was anticipated. In general, the best results in this series followed pneumonectomy in cases of bronchostenosis and thoracoplasty failure, and lobectomy in those patients who might otherwise have been treated by thoracoplasty.

Overholt et al²¹ also discussed pulmonary resection in the treatment of pulmonary tuberculosis. They mentioned the importance of the presence or absence of endobronchial tuberculosis in deciding the type of operation to be performed. They believe that bronchoscopy should be performed routinely following resection to ascertain the condition of the bronchial stump.

Broncholithiasis Barrett²² states that the term broncholithiasis is defined as the formation of calculi in a bronchus and that it has become diagnostic for any patient with a bronchial calculus. It has been stated that tuberculosis is the disease in which broncholiths are likeliest to arise. The symptoms are those of bronchial obstruction. In

all cases in which broncholithiasis suspected, a bronchoscope examination should be made

Clerf, Fox and Fields,¹ have reported 10 cases of broncholithiasis originating from calcified caseous tuberculous areas in the pulmonary parenchyma or lymph nodes, from inspissated pus of a lung abscess or an empyema and from calcified cartilages of the trachea and main bronchus. All patients were bronchoscoped, 8 patients expectorated a broncholith spontaneously, and in 5, one or more broncholiths were removed by bronchoscopy. Residual cylindrical bronchiectasis was the most frequent complication.

Zahn²³ has also reported a case of broncholithiasis. He believes that considering the frequency of calcification in tuberculosis, it is rather surprising to note the low reported incidence of broncholithiasis. In over 4000 cases of pulmonary tuberculosis the case reported was the only example of broncholithiasis.

Allergy. Lell²⁴ regards bronchoscopy as an aid in the diagnosis and treatment of allergic pulmonary disease. It is essential to rule out the possibility of foreign body before the diagnosis of bronchial asthma is made. In a series of 176 children observed bronchoscopically because they presented symptoms of asthma, 18 had foreign bodies in the respiratory tract, 5 had such objects in the esophagus, and 23 had other organic changes. The majority of the patients in status asthmaticus who were observed bronchoscopically showed a marked hemorrhagic and edematous appearance of the mucous membrane of the trachea and both main bronchi, with the presence of thick, tenacious secretion. In addition, most of the patients showed collapse of the posterior tracheo-bronchial wall. Bronchoscopic aspiration of the pulmonary secretion of patients in status asthmaticus who do not respond to medical treatment may often be a lifesaving measure. Oxygen administered through the bronchoscope during the aspiration relieves the dyspnea. One hundred and two patients with status asthmaticus were treated from one to twelve times each, or a total of 259 bronchoscopies with 1 death half an hour after bronchoscopy. The patient who died had previously undergone bronchoscopic treatment twice, with definite relief of symptoms. For six weeks during which the patient was in constant acute asthmatic attacks, bronchoscopy was deferred by a different attending physician. At that time the patient was unable to cough up any secretion, and as a last resort bronchoscopy was undertaken. The bronchoscopic examination revealed that the trachea and both the right and left main bronchi were completely filled with gelatinous, sticky secretions, of which at least 125 cc was aspirated. Immediately after the bronchoscopic procedure the patient seemed considerably relieved. He was being returned to the ward when he suddenly collapsed and stopped breathing. Post-mortem examination revealed advanced pulmonary

and generalized systemic changes. Despite the fact that the secretions had just been aspirated, all the smaller bronchi and bronchioles were occluded by organized plugs of mucus that could be stretched like a rubber band. To have helped this patient, the bronchoscopic aspiration should have been carried out when it was first recommended, and not four weeks later.

ESOPHAGOSCOPY

Congenital Anomalies

Vinson,²⁵ in a report on the incidence of esophageal disease in Negroes, calls attention to the fact that lesions in the esophagus that may have originated in congenital abnormalities were encountered more frequently in the White than in the Negro patients, whereas other lesions occurred with equal frequency, in accordance with the density of population. He suggests that congenital deformity may be rarer in Negroes because of the universal presence of the Rh factor in that race.

Gross and Scott²⁶ reported the case of a two-day-old male infant treated surgically by closure of the tracheoesophageal fistula and oblique anastomosis of the esophageal segments. The child did extremely well for a year and then had some difficulty in swallowing solid food. Esophageal dilatation was necessary. The child was in excellent health at twenty months of age.

Esophagitis

In a contribution to the roentgenologic diagnosis of limited esophagitis, Welin²⁷ states that the dominant symptom is progressive dysphagia. Substernal pain and eructation of phlegm were also noted in some of the patients. Esophagoscopy findings were divided into three different stages. In the initial stage the inflammatory process is less violent, and the changes are limited to an edematous, slightly bulging and easily bleeding mucous membrane. In the second stage the mucosa of the more or less narrowed lumen is inflamed and fibrin covered. In the final or healing stage, the mucosa is thin, pale and scarred, the wall being sclerotic and shriveled. The increasing infiltration produces progressive contraction of the lumen, which in the final stage may become completely obliterated. Esophagoscopy with biopsy is recommended. Welin presents numerous x-ray reproductions of the various stages and states that in these cases the question for roentgenologists is to find signs differentiating the condition from cancer. It should be pointed out, however, that no matter how smooth and benign the process may appear on x-ray study, esophagoscopy is definitely indicated in every case to rule out carcinoma by biopsy and also to carry out bouginage, which is usually a satisfactory form of treatment.

Benign Stricture

Benedict²⁸ has reviewed the cases of 44 patients with benign stricture of the esophagus. The fact that almost all patients were fifty years old made it exceedingly important to rule out carcinoma by esophagoscopy and biopsy. The disease is relatively infrequent in women. In this series there were 31 men and only 13 women. The benign stricture was associated with a hiatus hernia in 17 cases, with duodenal ulcer in 15 and with esophageal ulcer in 8. Treatment included bouginage through the esophagoscope, local application of sulfadiazine at the time of esophagoscopy, dietary management using only bland, strained foods with complete elimination of alcohol and tobacco and, later, the use of a bougie passed over a previously swallowed thread as a guide. It cannot be too often emphasized that blind bouginage is extremely dangerous. The results of proper treatment are usually satisfactory but depend on the severity of the inflammation and on the degree of co-operation from the patient.

In a recent case the treatment of benign stricture of the esophagus by esophagoscopy and bouginage was stated to be generally satisfactory.²⁹ The patient, however, had been operated on surgically, and the stricture resected without the benefit of esophagoscopy and bouginage. In this connection, Sweet²⁹ emphasized the danger of possibly missing a cancer of the esophagus by conservative treatment and also brought out the fact that there had been a recurrence of esophagitis in 1 or 2 cases following resection of a benign stricture.

Cardiospasm

Savinykh³⁰ considers esophagogastric anastomosis an important procedure in the treatment of cardiospasm, and states that more than a third of the patients with cardiospasm require operative procedures. I do not agree, believing that most cases are well handled by bouginage with the Hurst mercury bougie. Savinykh does not give adequate data regarding medical management and bouginage. It appears that some patients were operated on prematurely.

Grimson et al.³¹ reported 9 cases of achalasia treated by esophagogastric anastomosis or cardioplasty. Medical treatment had been used in most cases prior to operation, but it is not clear from the case reports that medical treatment with bouginage had been adequately carried out. Cardioplasty seems to have given fairly good results, but the follow-up period in some cases was rather short. I believe that most cases of achalasia or so-called "cardiospasm" can be treated fairly satisfactorily by a combination of general medical care, esophageal lavage, esophagoscopy if necessary, bouginage with the mercury bougie and sometimes judicious use of psychiatry.

Peptic Ulcer

Allison³² believes that peptic ulcer of the esophagus occurs when there is such a derangement of the mechanism of the cardia of the stomach that acid gastric juice flows back easily. The disorder that predisposes to ulceration is hernia of the stomach through the diaphragmatic hiatus into the posterior mediastinum. When the lower esophagus is being constantly bathed by acid from the stomach, a well defined series of changes is found. The first is a recurrent acute esophagitis, which passes on to a chronic esophagitis with recurrent acute ulceration. In the next stage an acute ulcer progresses to a typical chronic ulcer. The ulcer, with its surrounding induration, causes stenosis, and above this stricture there is intense superficial inflammation. Finally, a dense fibrous stenosis is produced. The treatment of a peptic ulcer of the esophagus is by the general medical measures used for ulcer of the stomach. When stenosis is present, repeated esophagoscopy and dilatations may be necessary. When blockage of the narrowed lumen is due to such foreign bodies as raisins, peas or fruit stones impacted in the stricture, relief is more marked, or there may be narrowing due to fibrous stricture from partial healing of the ulcer, in such cases dilatations often give a more prolonged result. The blind passage of bougies is mentioned only to be condemned. Allison states that on theoretical grounds it seems unjustifiable to apply the operation used for carcinoma of the esophagus to stenosis associated with an active ulcer and thus to leave a patient with the deformity that produced, or predisposed him to, the original ulcer. It was decided, therefore, that excision of the affected part of the esophagus was justifiable only if a means could be found for lengthening the esophagus and reducing the stomach below the diaphragm. A loop of small intestine isolated on its mesentery according to the method of Roux recently used extensively by Yudin, seemed to be the most practicable. The operation was first tried on a patient with carcinoma of the fundus of the stomach causing esophageal obstruction. Allison's conclusions are as follows:

Where the lower end of the organ is frequently subjected to digestion by acid gastric juice, peptic ulcer of the esophagus occurs. This happens where inefficiency of the diaphragm allows the stomach and abdominal esophagus to slide up into the mediastinum. Such herniation may be congenital or acquired. Where medical and assisted medical measures fail to relieve symptoms, the length of the esophagus may be restored and the stomach replaced in the abdomen. The size of the hiatus may be diminished to maintain the organs in their normal position. When chronic ulceration and fibrosis lead to inelasticity of the esophagus, reduction of the anatomic deformity may not be possible. The lower end of the esophagus may then be excised and continuity restored by a loop of small intestine on an elongated mesentery.

It seems probable that almost all cases of benign stricture of the esophagus, with or without peptic ulcer, can be treated by medical measures in addi-

tion to esophagoscopy and bouginage, and the indications for surgery in benign ulcers or strictures of the esophagus are therefore believed to be few.

Diaz and Riera²² reported 7 cases of esophageal peptic ulcer in 1 of which there was associated esophageal cancer. The roentgenologic and endoscopic findings were analyzed.

Lye Stricture

Hanckel²⁴ treated 4 cases of recent lye burns of the esophagus by the Salzer technic, and all patients recovered without stricture formation. The Salzer method advocates the early use of soft-rubber bougies in graduated sizes, filled with either mercury or lead shot, to prevent the formation of esophageal strictures. The details of the procedure are discussed. Esophagoscopy should be done in all cases but, to avoid perforation, should be avoided for several weeks after the burn. Barium studies under the fluoroscope are also indicated at frequent intervals.

Sweet²⁵ reported subtotal esophagectomy with high intrathoracic esophagogastric anastomosis in the treatment of extensive cicatricial obliteration of the esophagus. Three patients who had suffered cicatricial obliteration of a large portion of the esophagus as a result of chemical burns were treated by radical esophagectomy. In cases of intractable stricture of the esophagus resulting from chemical burns an esophagectomy followed by a high intrathoracic esophagogastric anastomosis is superior anatomically, physiologically and psychologically to any form of external esophagoplasty as a method of restoring the functional continuity of the upper alimentary canal.

Foreign Body

Bernstein²⁶ reported the removal of a *tortilla* from the esophagus — a *tortilla* is a thin, flat, unleavened cake, such as one of maize, baked on a heated iron or stone. At a point just below the cricopharyngeal muscle esophagoscopy revealed a translucent, doughy, grayish mass to be completely occluding the esophageal lumen. Because of the composition of the mass, it was believed that the usual hitting and grasping forceps would be of no avail. The esophagoscope was passed farther, and the mass circumscribed in its lumen, where it became firmly attached to the metallic walls and was withdrawn with the esophagoscope. The mass was 15 by 8 mm.

Holmes²⁷ presents the case of a ten-year-old boy who ate a piece of apple pie containing a fine steel wire that caused moderate pain on swallowing. X-ray study showed the wire to be to the left of the midline and at the level of the junction of the fourth and fifth cervical vertebrae lying transversely. The patient was given penicillin. Examination of the pharynx and esophagus under ether anesthesia was negative. Further x-ray films about

two weeks after the accident showed the foreign body to have migrated anteriorly, where it could be felt to the left of the thyroid cartilage. Under local anesthesia, it was extracted through a small incision.

Perforation

Grez²⁸ reported 2 cases of mediastinitis caused by perforation of the esophagus, with recovery after treatment with penicillin. In the first case the perforation followed instrumental dilatation of the esophagus for a stenosis after nitric acid ingestion, and in the other perforation occurred at the cricopharyngeal level after esophagoscopy. The importance of blood transfusion, intravenous therapy and penicillin therapy was emphasized. Before the advent of chemotherapy, mediastinitis was almost uniformly fatal but is now usually curable without surgery.

Spontaneous Rupture

Eliason and Welty²⁹ observed spontaneous rupture of a presumably normal esophagus in 3 cases during a one-year period. They regard the condition as more frequent than is usually appreciated. It is due to sudden increase in pressure. Rupture usually takes place during an episode of vomiting often precipitated by a bout of drinking or a heavy meal. The patient experiences sudden severe pain high in the upper abdomen or epigastrium or beneath the sternum. There may be a sensation of something tearing or giving way in the chest. On examination the patient is found to be obviously critically ill and in profound shock with extreme thirst. In the cases reported all the patients died. The authors believe, however, that with early diagnosis by roentgenography and esophagoscopy in questionable cases and by improved technics in anesthesia, transfusions and chemotherapy, recoveries will soon be reported.

Scleroderma

Rafsky and Herzig³⁰ have reported 2 cases of scleroderma with esophageal symptoms and cardiospasm. In one of these cases an esophagoscopic biopsy confirmed the diagnosis. Dysphagia was a prominent symptom in a seventy-three-year-old woman but was intermittent in a thirty-two-year-old man. In the first case x-ray examination showed the lower half of the esophagus to be markedly dilated, with spasm at the cardia of the stomach. In the second patient the radiologist demonstrated spasm of the lower third of the esophagus, with temporary obstruction at the cardia. Specific treatment was not discussed.

Olsen, O'Leary and Kirklin³¹ state that approximately 10 per cent of patients suffering from scleroderma have complaints referable to the esophagus — usually dysphagia — and sternal burning after meals. The

sclerosis of the connective tissue of the esophagus. Disturbances of the autonomic nervous system may play some part in the causation. The treatment consists of the passage of sounds over a previously swallowed thread as a guide.

Feeding-Tube Stenosis

Holinger and Loeb⁴² observe that severe laryngeal obstruction occasionally results from the routine use of nasal feeding or gastric-suction tubes. Fortunately, this complication is rare, it is so severe when it does occur, however, that it is essential to be aware of the possibility of this complication and to recognize its beginning symptoms at once. Four cases are presented. In 3, rubber nasal stomach tubes were used for four, seventeen and seven days, respectively, during which the patients complained of discomfort due to the tube. Symptoms increased with sore throat, pain radiating into the ears, pain on swallowing, hoarseness and finally dyspnea. Tracheotomies had to be done in these cases four to six weeks after removal of the stomach tubes. All the patients developed severe chronic laryngeal stenoses. One has been extubated, one wears a valve tracheotomy tube, and the third is still under treatment. The fourth patient died as the result of extensive carcinomatosis and mediastinitis. Post-mortem examination demonstrated the ulcer, which had not as yet caused laryngeal destruction.

A review of the literature reveals 24 recorded cases similar to those described above. Treatment consists of removing or changing the position of a feeding tube if the patient complains of a sore throat, especially if hoarseness or pain in the ears develops. Active treatment, aside from chemotherapy, consists of tracheotomy, drainage and subsequent laryngeal dilatation or plastic repair.

Tuberculosis

In spite of the fact that the esophagus may be continuously bathed by saliva containing tubercle bacilli, tuberculosis of the esophagus is rare. Hamburger⁴³ states that up to 1926 only 116 cases had been reported. Tuberculosis of the esophagus may develop as a result of the swallowing of infected saliva by direct propagation of tuberculosis of the larynx, by penetration of a tuberculous lymph node through the wall of the esophagus and by the blood stream or lymphatic vessels. The disease may be ulcerative or sclerotic, with or without stenosis. The upper third of the esophagus is involved most frequently, and the lower third least frequently. The best diagnostic results are obtained by endoscopy.

Varices

Tolan⁴⁴ reported several cases of esophageal varices treated by the injection of sclerosing solutions. He believes that the procedure has definite merit, but sufficient time has not elapsed to determine with accuracy its efficacy.

Carcinoma

Jacobsson⁴⁵ presents the case of a patient with carcinoma of the esophagus who was alive and free from evidence of tumor six years after x-ray treatment. He was fifty-eight years old when first seen in 1939. Biopsy showed squamous-cell carcinoma with low differentiation. More than six years after the treatment the patient was cured locally, had no difficulty in swallowing and had no noticeable metastases.

(To be concluded)

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., Editor

BENJAMIN CASTLEMAN, M.D., Associate Editor

EDITH E. PARRIS, Assistant Editor

CASE 33291

PRESENTATION OF CASE

First admission. A fifty-seven-year-old woman, an office worker, entered the hospital because of jaundice.

She had been in good health until two months before admission, when she had caught a cold and had had coryza and hoarseness lasting a few days. As the episode subsided she noted a persistence of lassitude and easy fatigability. Six weeks before admission anorexia and weakness became so severe that she discontinued work. After a shaking chill with nausea and vomiting a physician found the temperature to be 101°F and prescribed sulfadiazine tablets, of which the patient took eighteen without improvement. Three days later she had an attack of severe colicky pain in the right upper quadrant, without radiation, that lasted half an hour and was accompanied by slight nausea. She described this as the severest pain she had ever experienced. A second physician was consulted and found jaundice and an enlarged, tender liver. Subsequently, the patient noticed dark urine and stools that were somewhat light. The jaundice persisted, and a few weeks later pruritus developed. She had lost approximately 10 pounds during the illness.

The past history revealed no serious illness. The diet had been adequate. There had been no fat intolerance. She denied alcoholism.

Physical examination revealed a well developed and well nourished, slightly dehydrated woman in no acute discomfort. The skin and sclerae were moderately icteric. The heart and lungs were normal. The abdomen was slightly protuberant, with tenderness and voluntary spasm in the right upper quadrant. The liver edge was palpable six

fingerbreadths below the costal margin. The spleen was not felt. There was no fluid or edema.

The temperature was 102°F, the pulse 104, and the respirations 24. The blood pressure was 160 systolic, 85 diastolic.

Examination of the blood revealed a red-cell count of 4,000,000, with a hemoglobin of 14.2 gm, and a white-cell count of 9000, with a normal differential count. The specific gravity of the urine was 1.022, with a ++ test for albumin, a green test for sugar and a +++ test for bile. The stools were brown, several showing +++ guaiac tests. The total protein was 6.5 gm per 100 cc, with 4.0 gm of albumin and 2.5 gm of globulin, the cholesterol 263 mg, the cholesterol esters 127 mg, and the nonprotein nitrogen 26 mg per 100 cc, the van den Bergh reaction was 9.9 mg per 100 cc direct and 12.7 mg indirect, the amylase 25 units, and the alkaline phosphatase 19.5 Bodansky units per 100 cc. The prothrombin time was 27 seconds (normal, 15 seconds). The cephalin-flocculation test was normal, and the thymol turbidity 1.7 units.

A gastrointestinal series was normal except for a diverticulum in the third portion of the duodenum. The spleen was normal in size. The gall bladder contained five small, irregular calculi and filled with dye of diminished density. No calculi were visualized in the region of the common duct. A film of the chest showed areas of increased density occupying the right lower portion of the chest, consistent with collapse of the lower and the greater portion of the middle lobes, with a small amount of fluid.

During the first two weeks there were intermittent spikes in temperature to 103 and 104°F, with chills and a white-cell count rising as high as 34,000, with 95 per cent neutrophils. On a high-carbohydrate, high-protein and moderately low-fat diet, vitamin K and penicillin therapy, the patient gradually improved. The jaundice slowly disappeared. The temperature returned to normal, and x-ray examination showed improvement but considerable persisting density in the right lower portion of the chest.

An aspiration biopsy of the liver on the tenth hospital day showed bile stasis and mild cholangiolitis.

The clinical improvement was reflected by a return to normal of the prothrombin time and urine urobilinogen and by a disappearance of bile from the urine.

Thorotrast studies revealed no evidence of liver abscess and a normal-sized spleen

The patient was discharged to await improvement of the pulmonary condition

Second admission (four weeks later) At home she felt increasingly well, gaining 15 pounds She noted a persistent "catching" pain in the right upper quadrant, however, which seemed to improve after eating There had been no recurrence of jaundice or colic

Physical examination was negative except for a tense abdomen with an increased area of dullness in the right upper quadrant The liver edge was not palpable

On the second hospital day an operation was performed

DIFFERENTIAL DIAGNOSIS

DR ROBERT R LINTON May we see the x-ray films?

DR TOUFIC KALIL The biliary stones seen in this first film and on later films, appear to be contained within the gall bladder It was thought that one of them was a little too far from the others to lie within the gall bladder In the first gastrointestinal series, apparently, there was a great deal of food in the stomach, and the collection of barium was thought to be a diverticulum of the third portion of the duodenum A repeat gastrointestinal series with an empty stomach showed no evidence of a lesion — the "diverticulum" had disappeared The first chest films show an area of atelectasis in the right lower lobe, and a film taken later shows considerably more atelectasis and some fluid I do not believe that the middle lobe is definitely collapsed, but there is some collapse in the lower lobe, as well as fluid

DR HELEN S PITTMAN May I make a correction? My recollection is that the signs in the chest appeared after the liver biopsy and not spontaneously Dr Volwiler is in agreement with that statement, I believe

DR WADE VOLWILER Yes

DR LINTON This case presents a problem in biliary disease, and the following points are of interest. There was a short history of chills, fever, nausea and vomiting, dark urine, jaundice and light-colored stools Associated with these symptoms was a severe attack of pain in the right upper quadrant without radiation The patient had lost only 10 pounds in weight, and that had been coincident with the present illness She apparently had not had a chronic disease over a period of years that had caused her to be run down In my opinion a history of chills, fever, nausea and vomiting, jaundice, light, clay-colored stools and pain in the right upper quadrant is pathognomonic of cholelithiasis, choledocholithiasis and cholangitis I am slightly suspicious of these diagnoses, however, in view of the fact that the case is being discussed before this group In confirmation of the history and these diagnoses, however, are the facts that the patient was jaundiced on entry and that there were

tenderness and spasm and a questionable mass in the right upper quadrant, which was taken to be the liver The mass was felt six fingerbreadths below the costal margin It is possible that this was an inflammatory mass involving the gall bladder, but the physical examination seems so definitely to indicate that it was the liver that we must accept the statement The fact that x-ray examination of the gall bladder shows only a small gall bladder is also confirmatory In addition, the gall bladder was visualized by the Graham test — an indication that it was functioning to a certain extent I think that a completely inflamed gall bladder rarely concentrates dye, if the dye ever gets into it.

It is interesting that the spleen was not enlarged, since there have been a number of cases in which that has been demonstrated It could not be felt on physical examination and did not appear enlarged on the plain film, the Thorotrast examination, which should have visualized the spleen, again failed to demonstrate it I speak of that because it seems to me that one can fairly well rule out cirrhosis of the liver as the cause of the symptoms and the jaundice In addition, apparently, the patient did not have ascites, although that does not necessarily rule out cirrhosis, which can occur without ascites

The laboratory studies are of interest in that the hemoglobin and the red-cell and white-cell counts were normal, which indicate that this was not a neoplastic lesion The blood chemical findings, so far as I can tell, were essentially normal, except for the van den Bergh reaction, which was markedly increased, the direct reaction being 9.9 mg per 100 cc and the indirect 12.7 mg, giving a total of 22.6 mg, which in my experience indicates a rather severe jaundice The alkaline phosphatase was elevated — 19.5 units, which is far above normal What its diagnostic significance is, I am not entirely sure I do know that in obstructive jaundice an elevation of the alkaline phosphatase occurs The prothrombin time, which is of especial interest to the surgeon as a liver-function test, was elevated in this case, indicating considerable liver damage and a tendency toward hemorrhage following any surgical procedure

Another laboratory test that I consider significant was the +++ test for bile in the urine The fact that the stools were brown indicated that the patient did not have complete obstruction of the common bile duct The x-ray studies have been demonstrated to us, and we can see the stones in the gall bladder The chest film showed a slight amount of atelectasis before liver biopsy, indicating presumably that there was some process involving the right lower lobe It is possible that it arose from an inflammatory process beneath the diaphragm I think it unlikely that there was a pulmonary infarct I believe that the disease in the chest played no particular part in the clinical picture, therefore, I shall not consider the chest findings further

On the first admission it was of interest that the patient ran an intermittent fever associated with chills, the temperature going as high as 103 and 104°F. Associated with the fever was an elevated white-cell count, up to 34,000, indicating sepsis somewhere. After admission the patient was placed on a conservative regime and improved sufficiently so that it was not thought necessary to do an emergency operation.

The liver biopsy was essentially normal except for cholangitis and bile stasis. The patient finally returned a month after discharge, and an operation was performed.

It is my opinion that the diagnoses that best explain the history, the symptoms and the physical and laboratory findings are cholelithiasis, choledocholithiasis and cholangitis. A patient rarely has a so-called "Charcot type" of fever with such findings unless they are due to common-duct stone and associated infection in the biliary passages. Carcinoma of the common bile duct or pancreas cannot be entirely excluded. In my opinion, carcinoma of the biliary passages or head of the pancreas usually but not always produces complete biliary obstruction, whereas this patient had an intermittent obstructive jaundice, which in my experience is much likelier to be due to a ball-valve type of stone. I also consider the fact that her condition was fairly good on admission to indicate that she had not been suffering from an extensive malignant lesion.

Another condition that should be mentioned is congenital hemolytic jaundice, which usually occurs or becomes obvious much earlier in life. It is most unusual for a woman of fifty-seven years of age to become jaundiced for the first time because of congenital hemolytic jaundice. In addition, she had a normal-sized spleen, which again is most unusual in this condition. Another possibility is duodenal ulcer, which I believe should be ruled out chiefly on the basis of the x-ray findings and also by the fact that the history was not typical of duodenal ulcer. The diverticulum of the duodenum has been eliminated as a cause, and it could have been a cause only if it had contained some form of infiltrative process that involved the common bile duct by continuity. Infectious hepatitis might also be considered, but I do not believe that I have enough evidence to make that diagnosis. I have ruled out cirrhosis of the liver already by the fact that the patient had a normal-sized spleen and no ascites. I shall therefore stick to my original diagnoses: cholelithiasis, choledocholithiasis and septic cholangitis.

Dr. PITTMAN: We eventually thought as Dr. Linton did and requested a surgical consultation, with the same preoperative diagnosis. When this woman came in we seriously considered infectious hepatitis. Later on, we thought a good deal more of alcoholism because of a story that she and her husband had only egg and sherry for breakfast—we tracked that down but came up against a stone

wall. The patient was seen by Dr. Harold P. Himsworth, of London, and perhaps Dr. Dahl remembers what he said.

Dr. LEWIS K. DAHL: Dr. Himsworth made a diagnosis of infiltrative carcinoma involving the biliary radicles. He said that he had seen patients with carcinoma of the liver who appeared to be as septic as this patient and yet at autopsy had no sepsis. Therefore, he postulated that this woman had an infiltrative carcinoma of the biliary radicles—an intrahepatic infiltration.

Dr. VOLWILER: Another reason he made that diagnosis was that the liver appeared huge on the first admission.

CLINICAL DIAGNOSES

Cholelithiasis
Choledocholithiasis?

DR. LINTON'S DIAGNOSES

Cholelithiasis
Choledocholithiasis
Cholangitis

ANATOMICAL DIAGNOSES

Chronic cholecystitis
Cholelithiasis
Choledocholithiasis
Adenocarcinoma of ampulla of Vater

PATHOLOGICAL DISCUSSION

Dr. TRACY B. MALLORY: The operative note of Dr. Charles G. Mixer, Jr., was as follows:

Under nitrous oxide oxygen and ether anesthesia the abdomen was prepared and draped in the usual fashion and entered through a subcostal incision. Exploration of the abdomen was entirely negative except for the gall bladder which was densely adherent to the surrounding structures and was freed up with some difficulty. The bladder was slightly enlarged and contained a number of small stones in the ampulla and in the cystic duct and small stones could be palpated in the common duct. The gall bladder was removed from above downward. The cystic duct was large and was transected close to its entrance into the common duct. The common duct was then exposed. It was markedly dilated being approximately 1.5 cm. in diameter. It was incised; it had a thick wall and a number of small stones were obtained from it. When an attempt was made to pass a probe through the ampulla of Vater, however, it was found impossible to do so. On mobilization of the duodenum what was taken to be a stone about 7 mm. in size could be felt at the area of the ampulla at the site of obstruction. The stone searchers were used and there was a definite grating as if against a stone but the stone could not be grasped or withdrawn. It was therefore considered advisable to open the duodenum and explore the ampulla which was large and poufy being approximately 7 mm. across; it was surrounded by firm hard tissue, and in the center of the opening was a definite area of whitish, hard tissue which was biopsied. This was reported on the basis of a frozen section to be adenocarcinoma. It was therefore decided to proceed with a one-stage Whipple procedure.

The patient is still in the hospital, getting along fairly well, although she seems to have developed a trace of sugar in the urine. There had been occasional evidence of sugar before operation. Whether the resection of the pancreas was actually responsible for the diabetes is doubtful. She may have been

on the verge of diabetes before operation, which was enough to make the diabetes manifest. It has apparently been quite easy to control the glycosuria.

DR LINTON I do not know of any cases of diabetes developing after a Whipple operation.

DR ISAAC TAYLOR This patient had sufficient evidence of decreased glucose tolerance before operation to be considered diabetic.

DR DAHL Certainly, in animals, one can resect a much greater portion of the pancreas without producing diabetes.

DR LINTON This has been an extremely interesting and instructive case of obstructive jaundice. The operating surgeon, Dr. Mixer, is to be complimented on recognizing a carcinoma of the ampulla in the presence of common-duct stones. I still believe that the history, physical examination and hospital course are typical of choledocholithiasis and cholangitis and that the carcinoma was an incidental but, naturally, extremely important finding. I think that it is impossible to say whether there was any relation between the gallstones and the carcinoma. Dr. Mallory could perhaps enlighten us in this regard.

DR MALLORY The association between cholelithiasis and carcinoma of the gall bladder is close—in fact, it is rare to find a carcinomatous gall bladder in the absence of stones. I do not know of any figures concerning the association of cancer of the bile ducts and ampulla to the presence of stones in the common duct. Silent stones are, of course, frequent in the gall bladder, whereas they are certainly unusual in the common duct. It is possible that a stone must be present for years to induce the development of cancer.

CASE 33292

PRESENTATION OF CASE

A twenty-two-year-old man entered the hospital because of pain in the legs.

The patient had been in good health until three and a half years before entry, when he began to have bouts of bloody diarrhea associated with abdominal cramps, weight loss and weakness, but the symptoms were not severe enough to require hospitalization. A barium enema and gastrointestinal series three years before entry were negative. Despite a low-residue, bland diet, the patient continued to have similar episodes two or three times a year. His weight, which had been 180 pounds five years before entry, had decreased to 157 pounds a month before entry, and he was still having two or three semiformal bowel movements a day, although he had been improving since the last severe episode eleven months before admission. Five weeks before entry he was awakened by a sharp throbbing pain in the left leg, which seemed to center about the knee but sent "knife-like" radiations down to the toes and up to the hip. The pain persisted for about ten hours but was not

severe enough to keep him from walking, although he limped slightly. During the following week he felt well, but the pain returned and was even severer than previously. After two days in bed he was able to walk again, but the leg was weak and he had to limp, the pain gradually subsided over the course of a week. Three weeks before entry there was another severe exacerbation of pain, which persisted, forcing him to remain in bed except for visits to the clinic. Two weeks later he began to have pain in the right hip, subsequently radiating up and down the leg, similar to that on the left side. Aspirin gave only partial relief. On the day before entry he began to have pain in the jaw. At no time did he have swelling, redness, warmth or tenderness in any of the joints. Since the onset of the pain his appetite had been poor, and he had lost another 10 pounds in weight. He had been feverish but had had no real chills.

The patient had worked for six years as a ship-fitter in the Navy Yard. He did welding and used end lead intermittently as a plumber would. He disliked the work and complained of great fatigue. Six months before entry he took a job tinting photographs and continued with this work until the present illness.

Physical examination disclosed a patient who appeared acutely ill and was pale and sweating profusely, he complained of a dull, steady ache in both hips, as well as pain in the lower left teeth and stiffness in both temporomandibular joints. The heart was normal. There were dullness, decreased breath sounds and decreased tactile fremitus over the left portion of the chest. The abdomen was somewhat distended and firm, but not tympanic or tender. The muscles of the left thigh and leg were diminished in volume when compared with the right. Examination of the cranial nerves was negative, except for numbness to pinprick over the lower lip. The arms and legs were weak, the legs more so than the arms, and the quadriceps muscles were weaker than other groups. The patient was unable to raise the left leg off the bed, and the right was raised with some difficulty. There was no muscle tenderness. The knee jerks were absent. The arm jerks, hamstring and ankle jerks were normal, as were the abdominal and plantar reflexes. Sensation was normal except for the lower lip.

The temperature was 101°F, the pulse 120, and the respirations 20. The blood pressure was 150 systolic, 70 diastolic.

Examination of the blood revealed a red-cell count of 4,300,000, with 11 gm of hemoglobin, and a white-cell count of 7800, with 72 per cent neutrophils. The smear showed considerable polychromatophilia and basophilic stippling. Examination of the urine was negative, including a Watson test for uroporphyrin. The stools were soft and brown and gave a positive guaiac test. Repeated blood cultures were negative, as were a blood Hinton test and agglutination tests for typhoid fever and brucellosis.

The total protein was 6.9 gm per 100 cc, with an albumin of 4.03 gm and a globulin of 1.98 gm, the nonprotein nitrogen 22 mg, the phosphorus 3.2 mg and the alkaline phosphatase 4.2 Bodansky units per 100 cc. The cephalin-flocculation test was negative, and the van den Bergh reaction was normal. The prothrombin time was 17 seconds (normal, 15 seconds). Examination of the spinal fluid was negative.

X-ray examination revealed fluid in the left side of the chest and extending over the right lung in lamellar fashion. There was an area of increased density in the cardiophrenic angle on the left, which on lateral view seemed to be against the interlobar septum in the lower lobe. The abdomen was normal. The lumbar spine showed flattening of the lumbar curve. The knees were normal. An electrocardiogram was normal. A bone-marrow smear showed normal erythropoiesis and myelopoiesis. The gastric juice contained no acid.

On the second hospital day examination showed shifting dullness and a definite fluid wave in the abdomen. On the fourth hospital day a thoracentesis in the left posterior axillary line produced 50 cc of turbid yellow fluid, which became blood tinged as the tapping progressed. The specific gravity of the fluid was 1.019. The white-cell count was 100,000, with 5 per cent neutrophils, 25 per cent small lymphocytes and 70 per cent large mononuclear cells. No organisms were found by gram and Ziehl-Neelsen stains. On the seventh hospital day the patient appeared much worse, although he had been receiving 2 gm of streptomycin a day for three days. He complained of pain in the legs, back, abdomen and chest. The temperature was 102°F, and the pulse 160. A friction rub was heard in the left axilla. He was started on 400,000 units of penicillin a day. On the ninth hospital day a pentoneoscopy was performed. Two liters of turbid, rose-colored fluid, with cytologic findings similar to those in the pleural fluid, were removed. Acid-fast smears were negative. The liver was found to be slightly enlarged, with a rounded, everted edge. No tubercles or tumor was seen. On the fifteenth hospital day the temperature reached 106°F, and the white-cell count had climbed to 28,000. The blood smear showed some abnormal primitive stem cells, some late myelocytes and a few nucleated red cells. The patient gradually failed, and died on the seventeenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR JAMES B. TOWNSEND: This patient had a history of abnormal intestinal symptoms for more than three years before he entered the hospital for the terminal illness. May we see the x-ray films?

DR TOUFIC KALIL: This, apparently, is the area of increased density against the interlobar septum in the lower lobe.

DR TOWNSEND: Do you think that it is intrapulmonary and not in the pleural cavity?

DR KALIL: Yes, there is also pleural fluid.

DR TOWNSEND: Not so much fluid as I anticipated clinically.

DR KALIL: Not at that time. Apparently the patient became sicker.

This portable film taken at the bedside shows an increase in the amount of pleural effusion on the left and not much of anything else. This is a film of the abdomen taken at that time, showing an increase in the amount of peritoneal fluid.

DR TOWNSEND: The films of the old barium enema and gastrointestinal series are not here, I imagine.

DR KALIL: No.

DR TOWNSEND: Thoracentesis produced 50 cc of fluid. That is a small amount. I wonder whether it was a diagnostic tap to test the fluid or an attempt to get more.

A PHYSICIAN: It was a diagnostic tap.

DR TOWNSEND: The specific gravity was 1.019, which indicates an exudate. The white-cell count was 100,000. It must have been a turbid fluid. This was a mononuclear and not a polymorphonuclear type of fluid.

Was anything found on culture?

A PHYSICIAN: No.

DR TOWNSEND: I do not believe that I shall be able to reach an accurate diagnosis in this case. There are several possibilities that are worthy of discussion, however.

To recapitulate, this young man had been ill for three and a half years, starting with abdominal symptoms including recurring attacks of bloody diarrhea, which progressed to more or less continuous diarrhea, at least for the last few months. He was brought to the hospital by the occurrence of neurologic symptoms: pain in the legs, with weakness and apparent atrophy of the legs and with loss of knee jerks but with the other reflexes essentially normal. The neurologic symptoms were referred to various parts of the body, including the jaw and the lower lip. There is no description of any local inflammatory condition, however, in the region of the mouth or jaw to account for these symptoms. On admission he had fever and presumably had been running an elevated temperature for some weeks before that. He had lost over 30 pounds in weight. Although he had no complaints referable to the chest, the striking physical finding on entry was the presence of fluid in the left pleural cavity, which increased during the hospital stay. The character of the fluid is described, and while the patient was in the hospital considerable fluid developed in the abdomen of the same character as that in the chest. The patient then had a high fever and failed in spite of the use of streptomycin and penicillin. All attempts to find an infectious agent were apparently unsuccessful, and the patient died. Shortly before death the blood stream showed something that had not been present previously — namely, a few nucleated red cells and a few primi-

tive stem cells. Possibly, this was merely a terminal event in a patient extremely ill with other disease that had nothing to do with the hematopoietic system, although we must pay attention to these findings. These were found two days before death. A bone-marrow biopsy was performed, presumably shortly after admission and not close to the time of death.

This patient had generalized symptoms referable to the gastrointestinal tract and the nervous system, evidence of a disturbance in two of the serous cavities and, finally, a blood disturbance, which may or may not have been significant. We must consider three general categories of disease into which this case might fall.

Could there have been some type of neoplasm? The history is rather long for neoplasm in a young man, but there is one category of neoplasm, lymphoblastoma, in which a survival of three and a half or four years is possible. I believe that it is possible for some type of lymphomatous disease to cause most of the symptoms. Bloody diarrhea does not occur frequently in lymphomatous disease, but there are lymphomas of the intestines, particularly of the small intestine, that do bleed and can produce diarrhea and pain. Certainly, lymphomatous disease can cause a neurologic type of disturbance similar to what this patient had. If there is infiltration of the vertebrae, particularly with involvement of the spinal roots as they emerge from the vertebrae, severe pain and atrophy and changes of the type described in this case can occur. Lymphoma can involve the serous cavities. I do not know that I have seen it involve both the pleural and the peritoneal cavities, but I see no reason why this should not be possible. In the last two days of life there was evidence of a blood disturbance suggesting a neoplastic disease—namely, the appearance of nucleated red cells and the primitive stem cells. It is possible that this man had a lymphomatous process, call it “aleukemic leukemia” or whatever you will—something that had remained latent for a long time and finally, in the last few days, showed up in the blood. Nucleated red cells rarely occur even in the terminal stages of any severe type of disease except neoplasm involving bone marrow unless profound anemia is present, which was not so in this case. Nucleated red cells occur quite regularly in the course of any type of leukemia.

The second category of disease is some type of chronic infectious process, a form of granuloma, such as tuberculosis, actinomycosis, blastomycosis or one of the other granulomatous processes. We should also consider tularemia. Tularemia rarely runs a course so long as this. There is a variety of tularemia in which there is no presenting local lesion from which the organism has entered, it is believed that it can infect through the gastrointestinal tract. I have never heard of a case that went on with chronic diarrhea but certainly pulmonary and

pleural lesions occur and the findings may be fairly similar to those in the case under discussion, I think that tularemia is a remote possibility, however.

Every effort was made to locate tubercle bacilli in both the pleural and the abdominal fluid, with no success. There is nothing that I can see in the chest film to suggest tuberculosis of either the apical or the miliary type. If this was tuberculosis, it was a general tuberculosis, and I should expect it to be miliary. Moreover, the normal spinal fluid does not indicate the usual terminal meningitis, which is present in generalized miliary tuberculosis. Dr. Mallory is looking at the x-ray film. I wonder if he sees anything there that I do not see. The roentgenologist did not point out anything that looked like miliary tuberculosis. In spite of these negative findings we have all been caught on generalized tuberculosis, whether miliary or not, and I think that it is a possibility that cannot be excluded. The intestinal symptoms are consistent with it, and I think that practically everything in the case is consistent with that possibility, including the blood changes on the last two days of life. I have seen a patient die of generalized tuberculosis who in the last three or four days of life showed a myeloid picture closely resembling lymphatic leukemia and who was considered not to have leukemia—it was believed that the blood changes were due to extensive tuberculosis, even though this did not apparently involve the bone marrow.

I see no evidence on which to base a diagnosis of actinomycosis. An intestinal lesion that had gone on for that length of time from actinomycosis would undoubtedly have produced a fistula. I think that the pleural fluid would probably have been examined, and the examiners should have been able to find the organism. I see nothing on which we can base the diagnosis of blastomycosis or torulosis, particularly the latter, which does involve the meninges but in which the organism can usually be found. There may or may not be many cells in the spinal fluid. Torulosis usually produces meningeal symptoms, which this patient did not have.

The third category of disease in which widespread symptoms occur is the so-called “collagen-vascular group,” including such conditions as periarteritis nodosa and lupus erythematosus. These may go on for a long period and may cause widespread symptoms involving the muscles, as in this patient. I do not know whether they cause bloody diarrhea, however, and I cannot on this picture make a diagnosis of periarteritis nodosa, lupus erythematosus disseminatus or scleredema, although these possibilities should be mentioned.

In closing I am not at all sure what the diagnosis is, but I shall put as my first choice, lymphoma, and as my second, generalized tuberculosis.

DR. WYMAN RICHARDSON: This was a complicated case. I saw the patient only twice in consultation,

when Dr F D Adams was on service I am sorry that he is not present. Since the case was so complicated I said that I would simplify it. It is easy to simplify things by looking at the blood smear. I saw the patient shortly after admission and said that there was a great deal of red-cell regeneration and that it was not compatible with the usual types of sepsis, including tuberculosis. I do not know now what the answer is.

There were three things that I thought of: hemolytic anemia, marrow infiltration and blood loss. The blood loss did not seem to me to be sufficient. There was no evidence of hemolytic anemia. Although the question of lead poisoning came up, I could not see how it could account for the pulmonary picture. That left invasion of bone marrow by tumor, and because of the abnormal white cells, I said that I favored marrow disease, perhaps of the Hodgkin's-sarcoma type or some other rapidly progressive disease involving the marrow. I saw the patient a few days before he died. With this extreme outcropping of immature stem cells, which I could not identify, and some nucleated red cells and identifiable myelocytes, I was fairly certain that he had subacute myelogenous leukemia with a hopeless outlook. I did say, however, not being able to identify the primitive stem cells, that the myelocytosis might be due to marrow encroachment and that I should consider some other type of neoplastic cells, such as those of a Hodgkin's sarcoma. So far as the "group diseases"—lupus erythematosus and so forth—are concerned I have seen some queer pictures in them, but since we do not know what we are talking about when we discuss that group, what is the use of saying anything?

Dr TRACY B MALLORY I should like to ask the roentgenologist if he can see anything in the superior mediastinum in this film.

Dr. KALIL There is one other film, taken two weeks previously, that is perfectly normal, so that whatever developed was in that period. Both pulmonary arteries are prominent, particularly the one on the left. The only other shadow that might be difficult to explain is the one overlying the left pulmonary artery and possibly over on the right, but this is a supine portable film and difficult to interpret so far as that particular shadow is concerned.

CLINICAL DIAGNOSIS

Malignant lymphoma

Dr. TOWNSEND'S DIAGNOSIS

Malignant lymphoma

ANATOMICAL DIAGNOSIS

Malignant lymphoma, lymphoblastic type, involving small bowel, appendix, gall bladder, liver, mediastinum, retroperitoneal tissues and bone marrow

PATHOLOGICAL DISCUSSION

Dr MALLORY We found a 350-gm tumor mass in the region of the thymus, which I should think would have been visible on the x-ray films. There was tumor in innumerable other areas. One of the older tumors—and I think the primary one—was in the jejunum, 15 cm below the ligament of Treitz. It is quite conceivable that it had been present for three years and accounted for the early intestinal symptoms. There were multiple areas of involvement, chiefly of the serosa of the bowel, but the appendix was completely replaced by tumor, as was the gall bladder. The spleen was normal in size, and the liver was considerably enlarged and irregularly infiltrated with tumor, the large mass of tumor being centrally placed in the region of the falciform ligament and invading in both lateral directions from that point. The retroperitoneal tissues were widely invaded, involving the cortex of one adrenal gland and part of the pancreas, and there were multiple nodules in the kidneys. The bone marrow, which had shown only hyperplasia on biopsy a few weeks before death, showed marked infiltration with tumor cells. The spleen showed hematopoiesis but I cannot convince myself that it contained tumor cells. There were many nucleated red cells and myelocytes, which would adequately explain the blood picture. Histologically, we classified this as a lymphoblastic type of lymphoma. I think that the terminal involvement of the bone marrow was too irregular and hardly diffuse enough to warrant calling it leukemia. We did not explain the neurologic symptoms adequately. The spinal cord was normal, and unfortunately we did not have the peripheral nerves to study.

Dr CHARLES S KUBIK Considering the retroperitoneal involvement, I suppose that these pronounced neurologic symptoms, which had segmental distribution, are explained by tumor involvement of the spinal nerves in the region of the intervertebral foramen. This could have been missed at the time of post-mortem examination.

Dr RICHARDSON I should like to say that the terminal picture was not that of bone-marrow encroachment. The primitive stem cells in the peripheral blood were undoubtedly tumor cells.

Dr MALLORY Yes, I do not doubt that. Everything suggests that the tumor smoldered over a long period at a relatively low rate of growth and that there was rapid and widespread dissemination in the last few weeks of life, especially in the last few days.

MEDICAL GROUP PRACTICE

SPORADIC discussions of group practice, according to a paper published elsewhere in this issue of the *Journal*, have been plentiful since the report of the Committee on the Costs of Medical Care was issued in 1932. There has been, however, little critical analysis of factual data. Like the New England weather, group practice has evoked considerable comment with but little constructive action. Increasing interest, nevertheless, is being shown. This type of practice has been stimulated by both wars to the extent that 52 per cent of medical officers, according to a questionnaire of the American Medical Association in 1944, indicated their desire to engage in it after their return from service.

An attempt to define group practice shows that current conceptions of it range from a loose associa-

tion of physicians without organized financial arrangements to medical combinations, owned by one or more of the participating physicians, in which all income is pooled and divided. It is now generally accepted that common use of the facilities for practice, with the inclusion of two or more specialties, and the pooling and redistribution of incomes are necessary to fulfill the requirements.

Types of group practice are variously classified. Thus, one classification is based on ownership or sponsorship, as into private, industrial or hospital groups, and another according to the scope and type of medical service offered, whether into service groups in the strict sense, giving general care to patients, into reference groups furnishing only specialized care to referred patients or into diagnostic groups providing little or no treatment.

The chief argument in favor of group practice is the increasing complexity of modern medical practice. Listed against it are the fact that the general practitioner can still care for 85 per cent of all patients, the more or less cumbersome and often costly mechanism of such associations and the frequent impairment of the personal relation between physician and patient.

Let us hope that the study initiated last year by the United States Public Health Service, of which this paper is an introductory report, may go far toward giving the information we need. As the author writes, the answers must rest on "a foundation of factual data that is now lacking."

Various horse-and-buggy doctors have delivered a number of valedictory addresses in recent years. This does not mean, however, that their method of practice is entirely on the way out. We still have need of their modern prototypes among the various other forms of medical practice that a changing order will require.

A PASSING ERA IN MEDICAL HISTORY

Six amateur medical historians and book collectors greatly influenced the development of studies in the history of medicine in this country in the first three decades of the twentieth century. With the death of Edward Clark Streeter on June 17, at his home in Stonington, Connecticut, there

passed from the scene the last of the group, originally consisting of William Osler, William H. Welch, Harvey Cushing, Arnold C. Klebs, Casey Wood and Streeter. Only Streeter and Klebs were not actively engaged either in the practice of medicine or surgery or in laboratory research during most of their lives, but both Streeter and Klebs began their medical careers by seeing patients, one in general practice and the other as a specialist in tuberculosis. Osler was primarily a clinician, Welch a pathologist, Cushing a surgeon and Wood an ophthalmologist. In the late years of his life, Osler was actively engaged in the building up of a great library and became a collector of medical books unrivaled in his time. He found time, however, for scholarly studies as illustrated by his papers on Linacre and other medical worthies. Klebs turned more definitely to bibliographic research and the study of incunabula. His lifework culminated in an authoritative handlist of fifteenth-century books on medicine and science. Welch found time to write historical papers of great value, but he had little opportunity to do fundamental research in medical history similar to that done by Klebs and Streeter.

Streeter's work was largely in relation to the Renaissance and the development of medicine during the fifteenth century. He made a profound study of the doctors who practiced in both France and Italy during this period, but his particular interest was in the Florentine physicians. Few men had a wider knowledge of this field of medical history, and with a charming voice and manner, Streeter could talk for hours on a special subject, carrying his listeners along with him with so much enthusiasm that time was forgotten. So intimate was he with our medical forbears that he could bring to the imagination of the listener a vivid picture of Florentine medicine and the doctors who practiced it. Examples of his capacity to interpret the past, unfortunately, were seldom heard in public. It was in the quiet of his home, surrounded by books of his own choosing he knew so well, with a few friends and devoted students, that he was at his best. A section of his library, having to do with pest and fevers, was exhibited in Boston in 1921. The majority of his books ultimately found a fitting home in the library of the New York Academy of Medicine.

The amateur medical historian and book collector, such as these six men exemplified, added a distinct stamp of culture to American medicine. The pre-eminence of Osler and Welch naturally made them leaders in the field. Klebs was less known, since he lived in Switzerland the latter part of his life. He visited this country frequently, however, and being a superb letterwriter, he was in constant communication with his friends in America. Streeter was more of the retiring amateur type than any of the others. When he spoke in public, as he did infrequently, he made a great impression, and his few scholarly papers, particularly the studies on early anatomy with Garrison, will long be remembered.

These men began an era of great achievements in the field of medical history. A movement was instigated that is now widely expanding and changing the aspect of the advancing culture of medical thought throughout the country. Medical-history clubs have sprung up in many areas. Universities are taking recognition of cultural and historical studies in formulating their courses. But with the development of the professional historian of medicine, the era characterized by the amateur of great scholarship, charm, book-collecting instinct and long purse has largely passed with the death of the last of a great band of thoughtful men who made distinct contributions to our medical heritage.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

HOWARD—Allen R. Howard, M.D. of North Attleboro, died June 4. He was in his sixty-second year.

Dr. Howard received his degree from Cooper Medical College, San Francisco in 1911. He was formerly a major in the Medical Corps, United States Army. He was a fellow of the American Medical Association.

His widow survives.

KELLY—William P. Kelly, M.D. of Pittsfield, died April 15. He was in his seventy-seventh year.

Dr. Kelly received his degree from Albany Medical College in 1892. He was a former president of the Berkshire District Medical Society and was a fellow of the American Medical Association.

His widow and two daughters survive.

O'HARA—Francis J. O'Hara, M.D. of North Adams, died May 2. He was in his sixty-eighth year.

Dr. O'Hara received his degree from Georgetown University School of Medicine in 1904. He was a former mayor of North Adams and a former member of the board of health. He was medical examiner for the United States Aeronautical Bureau.

A son, a daughter, four grandsons, a brother and a sister survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

SENDING SPECIMENS TO DIAGNOSTIC LABORATORY

Physicians are reminded that the diagnostic outfits distributed when the Bacteriological Laboratory was located in the State House still bear the State House address and therefore will be delayed in reaching their destination unless the address is changed. All outfits on hand should be properly re-addressed to the Bacteriological Laboratory, 281 South Street, Jamaica Plain 30, Massachusetts.

If an early report is urgent, physicians are advised to send specimens by *special delivery* or *messenger*. This is particularly recommended during week ends and holidays, when mails are likely to be delayed.

Reports of new cases of diphtheria — as well as those of other diseases that depend on early bacteriologic diagnosis for proper treatment — are telephoned, without cost to the physician, to any part of the Commonwealth. Unless a telephone report is specifically requested, other reports will be forwarded by mail. All reports may be obtained by telephoning the laboratory (ARNold 5440).

EMERGENCY MATERNITY AND INFANT CARE PROGRAM

The Congress of the United States has passed legislation limiting the eligibility of the wives and infants of men in the four lowest pay grades of the armed services under the Emergency Maternity and Infant Care program to June 30, 1947, as follows:

If pregnancy occurs after June 30, 1947, the wife will not be eligible for payment for maternity care, nor will the infant be eligible for care during the first year of life.

All care for mothers and infants authorized on or before June 30, 1947, will be completed.

If pregnancy occurs on or before June 30, 1947, the wife will be eligible for payment for maternity care and her infant will be eligible for care during the first year of life. Applications for care of wives and infants eligible on or before June 30, 1947, may be considered for approval even though the application is submitted after June 30, 1947.

The prompt submission of outstanding medical bills will be appreciated by the Division of Maternal and Child Health, 73 Tremont Street, Boston.

MISCELLANY

CASH SICKNESS BENEFITS FOR RAILROAD WORKERS

A cash sickness-benefit system for railroad workers began to operate throughout the Nation on July 1. These benefits were added under the 1946 amendments to the Railroad Unemployment Insurance Act and provide partial compensation for wage loss due to disability, on the same basis as that due to unemployment. The system is administered by the Railroad Retirement Board.

All disabilities that prevent railroad employees from working, regardless of how or where they occur, are covered

under the program. In the first year of operations, about 300,000 of the 2,075,000 qualified railroad workers are expected to receive benefits, and the total amount of benefits is expected to reach \$36,000,000.

A physician's statement of sickness will be required before claims can be paid. It is believed that the program will require about six hundred and fifty thousand medical examinations a year. Employees are free to choose their own doctors, and any physician to whom an employee goes for examination or treatment may supply the information required as initial proof of an employee's claim.

The forms on which medical information will be requested from a physician are the "Statement of Sickness" and the "Supplemental Doctor's Statement." The first is intended primarily to obtain information at the beginning of each illness, and the second is intended to obtain additional information only when such information is needed later on in the same illness. The statements are designed to furnish, as simply and as conveniently as possible for the physician, the minimum information required for Board purposes.

The "Statement of Sickness" must be mailed to the appropriate regional office of the Railroad Retirement Board within seven days after the first day claimed as a day of sickness, otherwise the employee may lose part of his benefits. Claims for succeeding fourteen-day periods may be allowed for a predetermined period as indicated by the medical evidence on the doctor's initial statement, but in continuing illnesses supplemental information about the patient's illness may also be requested from the physician.

Claims will be filed and adjudicated in the regional offices of the Railroad Retirement Board. These offices are located in Atlanta, New York City, Cleveland, Chicago, Dallas, Kansas City, Minneapolis, Denver and San Francisco and serve the adjoining territories. Each will have a physician who will act as a medical consultant. Additional information about the program may be obtained from any of these regional offices or from district offices. For the New England states, the regional office is in New York City (341 Ninth Avenue), and the district office in Boston (1802 Post Office Building).

CORRESPONDENCE

MEDICAL JOURNALS WANTED

To the Editor: The American Red Cross has been requested by the International Red Cross to assist in securing the following copies of the *American Journal of Medical Sciences*:

February 1946	July 1945	November 1944
January 1945	January 1944	December 1944
March 1945	July 1944	November 1943
April 1945	September 1944	April 1942
June 1945	October 1944	April 1941

The copies are for the Netherlands Red Cross Society, which is desperately trying to help that country rebuild its war-shattered medical services.

The publishers have advised that these missing issues are not available. Those who have any of the above copies and are willing to donate to this worthy cause, are requested to send them to American Red Cross, Boston Metropolitan Chapter, Community Service to Camps and Hospitals, 17 Gloucester Street, Boston 15.

BOOK REVIEWS

Shock Treatments and Other Somatic Procedures in Psychiatry
By Lothar B Kalinowsky, M.D., and Paul H Hoch, M.D.
With a foreword by Nolan D C Lewis, M.D. 8°, cloth,
294 pp. New York: Grune and Stratton, 1946. \$4.50.

This is unquestionably a good book and may be considered the latest word on shock therapy. It surveys the history of somatic treatment for mental illnesses, discusses various methods of treatment in some detail and recounts the theories by which various men have tried to explain the success of

shock and convulsive therapy. The material is conscientiously documented. It is presented thoughtfully and yet with a minimum of personal bias—a characteristic that is especially rare among physicians who are practicing particular types of shock therapy.

Persons interested in deep psychology may regard the discussion of psychologic aspects of treatment as a little less than open minded, the hazards, complications and inadequacies of organic treatment are thoroughly outlined however, and the empirical nature of these treatments is acknowledged and the advantages (of which there are many) of the somatic approach honestly evaluated.

Drs. Kalinowsky and Hoch offer excellent general descriptions of the techniques of the different types of treatment (insulin shock, the convulsive therapies, combined insulin and convulsive treatment, other somatic nonsurgical treatments and prefrontal lobotomy) and the reactions of the patients during and after these treatments are thoroughly described from the physical and social points of view.

The point of the theoretical aim of treatment is left in question at the end of the book but perhaps one should not quibble over this, since expression of personal views was evidently not the entire intention of these authors. A fair-minded reader of this book cannot fail to be profoundly grateful that such a comprehensive survey of this important field has been made available in an up-to-date form.

The authors deserve to be congratulated on their well organized and distinguished performance in the writing of this book, as well as on the actual clinical work on which it is based. All this has obviously been a serious and important undertaking to them.

The Traumatic Deformities and Disabilities of the Upper Extremity. By Arthur Steindler M.D. In collaboration with John L. Marzler M.D. 4th cloth, 494 pp., with 443 illustrations. Springfield, Illinois: Charles C. Thomas 1946. \$10.00.

This excellent volume is a sad commentary on the state of the immediate surgery of trauma in this country. At least half the deformities and disabilities it describes should never have been allowed to occur and were the result of ignorance and neglect in primary treatment. Nowhere in the book, however, is this mentioned. The authors simply review their extensive experience in reconstruction and rehabilitation. Two hundred and sixty pertinent and well illustrated cases are presented. It is refreshing to note that not all these are surgical triumphs. The failures are often much more instructive than the successes. Personal experience is emphasized but the literature is thoroughly reviewed.

Other surgeons will not share the author's enthusiasm for certain procedures such as fascial reconstruction of the dislocated acromioclavicular joint and suspension operations for recurrent dislocation of the shoulder. A discussion of the British and American experiences with peripheral nerve injuries during World War II could have been included to advantage. Descriptions of operative technique are perhaps oversimplified and could encourage the inexperienced to attempt procedures that are often complex and trying in the most expert hands.

But these are minor criticisms and do not detract from the value of the book as a whole. It should be on the shelf of everyone whose practice includes surgery of the extremities.

BOOKS RECEIVED

The receipt of the following books is acknowledged and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Check and Double Check on Sickness Insurance. By J. Weston Welch B.S., M.Ed., instructor in economics and business law, Portland (Maine) High School. 8th paper, 62 pp. New York: Medical Society of the State of New York 1946.

Mr. Welch has prepared this pamphlet as a condensation from a large manual on the subject written for debate purposes. It is written in the form of questions and answers and is intended for the use of all persons called on to speak on the subject. It should prove useful for this purpose.

Medical Social Service in Tuberculosis Control. Federal Security Agency, United States Public Health Service. 8th paper, 22 pp. Washington: Federal Security Agency 1945.

The Tuberculosis Control Division of the United States Public Health Service is formulating a plan for medical social service and to assist in this undertaking an advisory committee of social workers was formed by the American Association of Medical Social Workers in October 1945. This pamphlet comprises the report of the first meeting of this group and defines the functions of the medical social worker as they are related to a tuberculosis-control program.

Outline of the Spinal Nerves. By John Favill A.B. M.D. clinical professor of neurology (Rush) University of Illinois College of Medicine and attending neuropsychiatrist, Presbyterian Hospital Chicago. 8th cloth, 190 pp., with 24 illustrations. Springfield, Illinois: Charles C. Thomas 1946. \$3.75.

Dr. Favill has provided full information on the motor functions of the spinal nerves. The material has been compiled from the recognized standard textbooks of anatomy and where there were disagreements the author made his own choice of data. The material is given in the form of lists since it has been found that tables are unsatisfactory in the presentation of full data concerning any single nerve or muscle. The text is in five parts: the roots, nerves and muscles, the neurologic aspects of clinical lesions of the muscles with an indication of the etiology of the lesions, the muscles, with their origins, insertions, functions, tests and indications of paralysis, the movements by regions and members showing the muscles and nerves involved and supplementary information concerning the lesions of the plexuses, causalgia, causes of neuritis, neuropathy and low back pain, a description of electrical tests of nerves and muscles and a list of muscular disorders. The volume is written as a companion to the author's manual on the cranial nerves published in 1933. The book is well published in every way except that an important list is printed on the lining of the back cover. Material of this sort should not be printed on the covers of a book since it is damaged or destroyed by handling and lost in rebinding. The manual should prove useful to neurologists and others interested in muscle lesions and should be in all medical libraries as a reference source.

Quantitative Chemical Chemistry Interpretations. By John P. Peters M.D., professor of internal medicine, Yale University School of Medicine, and Donald D. Van Slyke Ph.D. Sc.D., member of the Rockefeller Institute for Medical Research. Second edition. Volume I. 8th cloth, 1041 pp. Baltimore: Williams and Wilkins Company 1946. \$7.00.

This standard reference work has been completely rewritten and the wealth of material available has necessitated a rearrangement of the work into three volumes instead of the previous two parts, *Methods* and *Interpretations*. Because of the tremendous progress in recent years in clinical chemistry Dr. Van Slyke has become responsible for the part on methods and Dr. Peters for the part on interpretations. This first volume of *Interpretations* covers the subjects of energy metabolism, chemistry, physiology and clinical complications of the carbohydrates, including diabetes, lipids and protein metabolism. The original objective of the first edition published in 1931 has been adhered to—namely to discuss the substances that are important in clinical medicine and for whose determination suitable quantitative methods are available. A comprehensive bibliography is appended to each part, and all significant original sources are quoted. The bibliography of the lipids alone comprises 979 references. An excellent index concludes the volume. The text is well printed with a good type on light paper resulting in a volume that is not too heavy for its size. This authoritative reference work should be in all medical and hospital libraries and in the libraries of clinicians.

Progress in Gynecology. Edited by Joe V. Meigs M.D., clinical professor of gynecology, Harvard Medical School, chief, Vincent Memorial Hospital, the Gynecological Service of the Massachusetts General Hospital, surgeon, Pondville Hos-

pital, and gynecologist, Palmer Memorial Hospital, and Somers H. Sturgis, M.D., chief, Vincent Memorial Hospital Laboratory, and assistant surgeon, Massachusetts General Hospital 8°, cloth, 552 pp., illustrated New York Grune and Stratton, 1946 \$7.50

This composite volume is the work of seventy-one authorities, each writing on a special subject. The objective of the work is to provide the latest knowledge of gynecology for the purpose of refreshing and bringing up to date the men who were with the armed forces. The volume should also prove useful to surgeons, gynecologists and physicians who desire to keep abreast of the times. The material is well organized and arranged in the following divisions: growth and physiology, diagnostic methods, functional disorders, interrelations of endocrine glands, sterility and reproduction, infections and their treatment, benign growths, malignant growths, operative technic and preoperative and postoperative care. A good index completes the volume. The type and printing are good, but the paper is too heavy for the size of the book. The volume is recommended for all medical libraries and the libraries of gynecologists.

National Formulary. Prepared by the Committee on National Formulary under the supervision of the Council by the authority of the American Pharmaceutical Association. Eighth edition. Official from April 1, 1947. 8°, cloth, 850 pp. Washington: American Pharmaceutical Association, 1946 \$7.50. (Distributed by the Mack Publishing Company, Easton, Pennsylvania.)

This standard essential reference work has been thoroughly revised and enlarged by the addition of one hundred and eighty-eight new drugs and preparations. Many formulas and standards have been continued in this new edition for *USP XII* drugs not admitted to *USP XIII*. This edition represents the results of four years of planning and work by the committee, the staff of the association's laboratory and hundreds of collaborators. In this edition, for the first time, titles in English precede the Latin titles. The volume maintains the excellence of publication of the previous editions.

Charles-Édouard Brown-Séquard. A nineteenth century neurologist and endocrinologist. By J. M. D. Olmsted, M.A. (Oxon), Ph.D., D.Sc., professor of physiology, University of California. 8°, cloth, 253 pp., with two portraits. Baltimore: Johns Hopkins Press, 1946 \$3.50.

This biography of Brown-Séquard, born Charles-Édouard Brown, relates the story of his life in Mauritius, where he was born in 1817, in France, where he received his medical education, in the United States, where he lived for a time, and again in France, where he became a professor at the Collège de France and died in 1894. It contains a wealth of material, but pertinent dates and facts are difficult to find, since they are lost in the narrative. Interwoven with the story of Brown-Séquard's life are commentaries on contemporaries and the relation of their work to that of Brown-Séquard. Despite its difficult style the book should be in all medical-history collections.

Quarterly Review of Obstetrics and Gynecology. Volumes I, II and III, 1943-1945, reprinted. 8°, cloth. Washington: Washington Institute of Medicine, 1946 \$25.00 (set).

This set of volumes comprises 2193 pages containing 3663 abstracts of noteworthy articles published in English during 1943-1945. The abstracts are short and contain the essential points of the articles. The publication is excellent in every way. The publisher reprinting these volumes long out of print has made possible their acquisition by interested physicians and specialists. The reprinting was limited to a thousand sets, about two thirds of which had been sold in December, 1946.

The Essentials of Obstetrics and Gynecology. By William Albert Scott, B.A., M.B., F.R.C.S. (Can.), F.R.C.O.G. (Eng.), professor of obstetrics and gynecology, University of Toronto, and H. Brookfield Van Wyck, B.A., M.B., F.R.C.S. (Can.), F.R.C.O.G. (Eng.), assistant professor of obstetrics and gynecology, University of Toronto. 8°, cloth, 390 pp., with 91 illustrations. Philadelphia: Lea and Febiger, 1946 \$5.50.

The authors have based this manual on the course of lectures given to undergraduates in the University of Toronto

Medical School. They have succeeded in condensing the fundamentals of their subjects into a comparatively small volume. The material is well organized. Obstetrics is divided into normal, abnormal and operative. Gynecology is arranged by organs, followed by general subjects and operative procedures. The volume is well published, with a good type, paper and format, and should prove useful as a manual of the subjects.

Trabajos del Dispensario Antituberculoso Central y del Sanatorio Antituberculoso de Ofrá, de Santa Cruz de Tenerife, Canarias (España). Part VII, 1944-1945. 8°, paper, 356 pp. Santa Cruz de Tenerife: Imprenta Católico, 1946. No charge.

This volume contains a number of papers on the various aspects of tuberculosis, including diagnosis, treatment and association with other diseases. The following subjects are worthy of special notice: the psychopathology of the tuberculous patient, epidemic hepatitis and tuberculosis and a report of an epidemic in a tuberculosis sanatorium with a study of the effect of the hepatitis on the tuberculous patient. The first part is devoted to the statistics of the institution. The volume should be in all large medical libraries and in all special collections on tuberculosis.

Heparin in the Treatment of Thrombosis. By J. Erik Jorpes, M.D., reader in biochemistry, Caroline Institute, Stockholm, Sweden. With a foreword by J. R. Learmonth, C.B.C., Ch.M., professor of surgery, University of Edinburgh. Second edition. 8°, cloth, 260 pp., with 21 illustrations, 2 color plates, 1 portrait and 30 tables. New York: Oxford University Press, 1946 \$6.50.

This new edition of a special monograph, first published in 1939, is brought up to date, and the recent experience in the use of heparin in thrombosis and embolism is summarized. The work is divided into two parts: the first considers the chemistry and physiology, including a chapter on dicoumarol; the second is devoted to the use of heparin in the treatment of thrombosis, latent thrombosis and pneumonia and the use of dicoumarol, some aspects of pathogenesis and the social aspects of thrombosis. The text is well documented with statistical tables, and a long bibliography of eighteen pages concludes the volume. The material is well organized and the book is well published in every way except that a heavy coated paper is used when a lighter paper would be more suitable for such a small volume. (Coated and silica-filled papers when wet become as solid as concrete.) The monograph is recommended for all medical libraries and to all physicians interested in vascular diseases.

The Treatment of Diabetes Mellitus. By Elliott P. Joslin, M.D., Sc.D., medical director, George F. Baker Clinic, New England Deaconess Hospital, Boston, and consulting physician, Boston City Hospital, Howard F. Root, M.D., physician-in-chief, New England Deaconess Hospital, and associate in medicine, Harvard Medical School, Priscilla White, M.D., physician, New England Deaconess Hospital, and instructor in pediatrics, Tufts College Medical School, Alexander Marble, M.D., physician, New England Deaconess Hospital, and instructor in medicine, Harvard Medical School, and C. Cabell Bailey, M.D., physician, New England Deaconess Hospital, and research fellow in medicine, Harvard Medical School. Eighth edition, thoroughly revised. 8°, cloth, 861 pp., with 13 figures, 117 tables, 1 map and 1 chart. Philadelphia: Lea and Febiger, 1946 \$10.00.

This authoritative treatise is based on the experience of Dr. Joslin and his colleagues over a period of forty-five years, covering the observation of 29,000 patients with diabetes and glycosuria. The text is thoroughly revised, and emphasis placed on statistics, physiology and pathology, as well as treatment. A chapter on alloxan diabetes is included, and the role of this chemical in the causation of diabetes is discussed. The fact that there are one million diabetic patients in the United States makes the disease a major social problem to be faced by the public, the medical profession and the Government. The volume is well published and should be in every medical library and in the libraries of practitioners. It is an outstanding work on an important subject.

RECURRENT CANCER OF THE COLON AND RECTUM*

Report of Cases with Favorable Results Following Radical Surgery

J. E. DUNPHY, M.D.†

BOSTON

ADVANCES in the treatment of cancer of the colon and rectum consist largely of measures that have extended the amount of resection.¹⁻⁴ In early lesions, such radical surgery offers the best assurance of cure. In advanced lesions, it permits the removal of growths that were formerly regarded as totally inoperable. Even when cancer recurs it can be removed by a second attempt at radical surgery. Once a properly executed resection has been done, however, there is a tendency for the surgeon to believe that the die has been cast. Because most recurrences are beyond the scope of surgery, all recurrences are apt to be considered hopeless. Removal of such lesions is regarded merely as a surgical feat without benefit for the patient. It is the purpose of this paper to point out that this attitude of pessimism is not entirely justified.

It has been proposed that since surgery is the only way to treat cancer of the colon initially, it should be employed whenever possible in dealing with recurrences.² If there is no positive evidence of distant metastases or generalized peritoneal seeding, reoperation should be considered regardless of the extent of the first operation, the histologic character of the growth or the apparent fixation of the recurrence. The following cases are illustrative of what may be accomplished.

CASE 1. A G. A 36-year-old woman was admitted to the hospital in August, 1936, because of acute intestinal obstruction following abdominal cramps and rectal bleeding of 3 months duration. Laparotomy disclosed a constricting lesion of the sigmoid, producing complete obstruction. A right transverse colectomy was performed. Postoperatively a large pelvic abscess required colpotomy. One month later resection of the sigmoid with end-to-end anastomosis was performed. The convalescence was uneventful and the transverse colectomy was closed 2 weeks later.

Biopsy of the tumor revealed an adenocarcinoma that was moderately rapidly growing; the regional lymph nodes were extensively involved.

The patient re-entered the hospital 18 months later because of crampy abdominal pain of 3 months and rectal bleeding of 2 weeks' duration. There was a large tender

fixed mass in the left lower quadrant and pelvis. It felt like a large ovarian tumor fixed to the lateral wall of the pelvis. At reoperation a solid tumor mass involving the sigmoid, mesentery, retroperitoneal tissue and left adnexa was resected. A permanent colectomy was performed. The rectal stump was closed below the level of the peritoneum.

Pathological examination disclosed a solid mass of adenocarcinoma. No lymph nodes were identified. The growth histologically appeared to be more rapidly growing.

The patient re-entered the hospital 4 years and 5 months later for repair of a ventral hernia. She was asymptomatic. At operation no definite evidence of tumor was found. A small egg sized nodule along the course of the ureter was thought to be a mass of scar tissue. She re-entered the hospital 1 year later with acute intestinal obstruction of 2 weeks duration. She died of peritonitis following a laparotomy for small bowel obstruction due to recurrent cancer.

Autopsy. Post mortem examination revealed a solid mass of rapidly growing adenocarcinoma involving the ureter, iliac artery and vein, psoas muscle, the colon, and many loops of small bowel. There was no tumor in the pelvis and no metastases in the liver.

The total survival after the second operation was 5 years and 5 months—the patient lived for 5 years and 2 months without symptoms.

The significant point about this case is not that a large recurrent tumor mass was arrested for over five years but that had the surgery been slightly more radical, a permanent arrest would have been accomplished. It is also remarkable that four years after the second operation, the recurrent growth was so small that it was not recognized as tumor and yet a year later there was a huge diffuse recurrence, as if for a time the lesion had remained dormant and had suddenly begun to grow again.

CASE 2. E. K. A 56-year-old man was admitted to the hospital in August, 1930, because of anorexia and diarrhea of 6 weeks duration and pain in the right lower quadrant and tenderness and swelling of a 35-year-old appendectomy scar of 3 days duration. There was a large abscess in the right lower quadrant, pointing in the old appendectomy wound although its etiology was not clear. Incision and drainage of the abscess were necessary. Two weeks later a barium enema showed a large filling defect in the cecum. A right colectomy was performed with an end-to-side ileotransverse colectomy (Fig. 1). The tumor had invaded the abdominal wall about the old appendectomy scar. The entire thickness of the parietes was generously excised in this area. Convalescence was uneventful.

Pathological examination disclosed an adenocarcinoma that had extended through and beyond the bowel wall. The regional lymph nodes were extensively involved. Histologically the tumor was growing slowly.

*Presented at a meeting of the Boston Surgical Society, December 2, 1946.
†From the Surgical Service of the Peter Bent Brigham Hospital.
Assistant professor of surgery, Harvard Medical School.

The patient re-entered the hospital $2\frac{1}{2}$ years later, complaining of pain in the right flank, loss of weight and a lump in the scar. Examination disclosed a large, ill defined mass that appeared to involve the abdominal wall. Some observers thought that it was a mass in the liver.

A large mass involving the abdominal wall and round ligament of the liver was found at the second operation. It was excised en bloc with the tissues of the abdominal wall (Fig 2).

Pathological examination disclosed a rapidly growing adenocarcinoma with local extension to the urinary bladder and ileum and many lymph-node metastases.

The patient re-entered the hospital 2 years later because of abdominal cramps and rectal bleeding. There was an ill

FIGURE 1 Case 2

This carcinoma of the right colon, involving the abdominal wall, was removed by a right colectomy. Note the abundant mesentery, indicating adequate removal of regional nodes, which were extensively involved.

The defect in the abdominal wall, which measured 12.5 by 10 cm. was closed by sliding over the left rectus and the right external rectus. Convalescence was uneventful.

Pathological examination revealed a solid mass of adenocarcinoma, no lymph nodes were identified. Histologically the tumor was observed to be invading tissue planes but was growing slowly.

The patient is alive and well without evidence of recurrence $6\frac{3}{4}$ years since the second operation.

CASE 3 D. R., a 52-year-old man, was admitted to the hospital in July, 1939, because of rectal bleeding, tenesmus and loss of weight for 18 months. A large fixed mass was palpable in the left lower quadrant. A barium enema showed a filling defect in the sigmoid, with direct extension to the bladder and terminal ileum. A right transverse colostomy and a side-tracking ileocolostomy were performed. Post-operatively, the patient developed a wound infection. Three weeks later resection of the sigmoid, terminal ileum and upper third of the bladder was performed. Convalescence was uneventful. The colostomy was closed 2 weeks later.

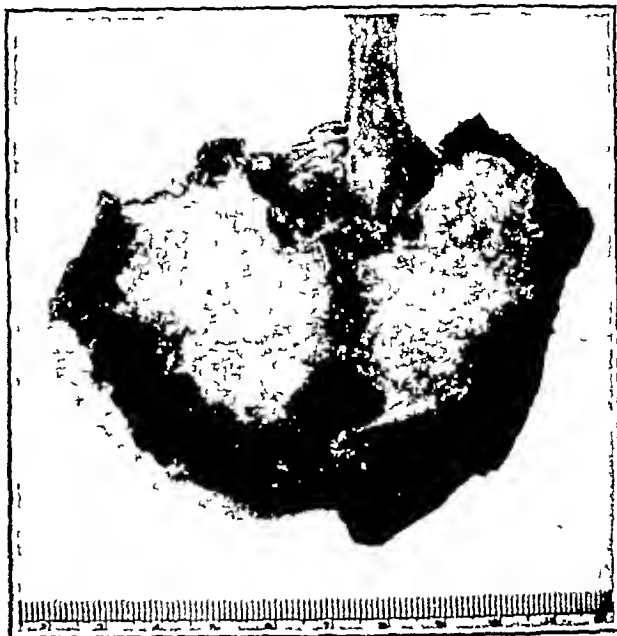

FIGURE 2 Case 2

This solid mass of recurrent adenocarcinoma, involving the abdominal wall and round ligament of liver, was removed two years after the first operation. The patient is alive and well six years and nine months after the second operation.

defined mass low in the left lower quadrant just at the base of the pelvis. A barium enema showed evidence of extrinsic

FIGURE 3 Case 4

This is a solid mass of adenocarcinoma involving the perineum and prostate two years after abdominoperineal resection. The patient was asymptomatic for four years after radical removal.

pressure on the sigmoid. At operation a mass of solid tumor was found to involve the sigmoid, mesentery, bladder, left ureter and retroperitoneal tissues, it was separated with difficulty from the iliac vessels. The ureter was resected, but because of lateral displacement it was sufficiently long to

permit an end-to-end anastomosis. A permanent colostomy was performed. The serosa over the posterior aspect of the bladder was removed with the tumor, but the bladder wall was not involved. Convalescence was uneventful.

Pathological examination revealed that the tumor was a mass of adenocarcinoma in situ that was involving the bowel wall. Histologically, it was extremely anaplastic with many lymph-node metastases.

The patient is alive and well without evidence of recurrence 5½ years since the second operation. The function of the left kidney is normal.

This was certainly an unfavorable case by ordinary standards. The tumor was rapidly growing, the regional lymph nodes were extensively involved, and the original removal had to include portions of the bladder and ileum. Under such circumstances, the recurrence might well have been viewed as being beyond the scope of surgery. Yet, in retrospect, this has proved to be one of the most successful cases.

CASE 4. R. F., a 68-year-old man was admitted to the hospital in February, 1940 because of bloody diarrhea of 3 months duration. Examination showed a large slightly fixed tumor in the left posterior wall of the rectum extending to within 2.5 cm. of the rectum. It was removed in one stage by an abdominoperineal resection. Convalescence was complicated by acute cystitis and an abscess in the posterior wound.

Pathological examination disclosed a slowly growing adenocarcinoma without lymph node metastases.

Eight months after operation a perineal recurrence was noted. Operation was not considered feasible. The perineal mass, however, increased in size, became painful and bled occasionally. The patient re-entered the hospital 22 months after the original operation. A radical perineal excision of the tumor, together with a total prostatectomy was performed (Fig. 3). Convalescence was uneventful except for urinary incontinence.

Pathological examination revealed a solid mass of adenocarcinoma; histologically, the tumor appeared to be more rapidly growing.

The patient remained asymptomatic for 4 years, although after 2 years there was evidence of a recurrence in the perineum for which he refused hospitalization. At present 5 years after operation he is bedridden with recurrent cancer.

The significant point in this case is again not the palliation of four years' duration but the fact that had reoperation been carried out sooner, an even more favorable result might have been obtained.

These cases have been selected as examples of what may be accomplished by a second attempt at extirpation of carcinomas of the colon and rectum that have recurred locally. Obviously, if there are distant metastases or generalized peritoneal seeding, such surgery should not be attempted. The results in these cases, however, suggest that a tumor that recurs locally without distant metastases is peculiarly amenable to surgery if it can be completely eradicated.

A review of the histology of the tumors in these cases provided no clue to why distant metastases had not occurred. There were extensive lymph-node metastases in Cases 1, 2 and 3, and in Cases 1 and 4 there was evidence of blood-vessel invasion. Nor was the rate of growth of the tumor a reliable guide to prognosis in the individual case. None of the tumors were exceedingly anaplastic, but in Cases 1 and 3 there was moderately rapid growth. Cases 2 and 4 were more slowly growing, but in Case 2 there was lymph-node involvement and in Case 4 there was blood-vessel invasion. In the present state of knowledge the histologic character of the original growth seems to constitute no reason for withholding surgery if the tumor recurs.

The possible role of inflammation in limiting the distant spread of these tumors occasions comment—in Cases 1, 2 and 4 there were local abscesses in and around the growth, and in Case 3 the tumor was of an extremely inflammatory character. A study of the histology of the tumors, however, provided no evidence to support this notion. Whether or not an inflammatory reaction sealed off the lymphatic vessels at the base of the mesentery is a problem for pure speculation and future observation.

The principal point to be stressed is that one must not give up in dealing with cancer.

CONCLUSIONS

Recurrent cancer of the colon and rectum is not necessarily hopeless.

Tumors that grossly and histologically appear unfavorable may recur locally without distant metastases.

If there is no positive evidence of distant metastases or generalized peritoneal seeding, reoperation should be considered in the treatment of recurrent cancer of the colon, regardless of size and apparent fixation.

Gratifyingly long periods of arrest may follow such operations.

INFECTIOUS HEPATITIS ASSOCIATED WITH PREGNANCY*

A Report of Four Cases

RALF MARTIN, M D,† AND FRANK C FERGUSON, JR, M D ‡

PORTLAND, MAINE

AN EPIDEMIC of infectious hepatitis began among the civilian population of Portland, Maine, during 1944, and has continued to date. Four cases occurred in pregnant women. Since this combination is rare, having occurred in only 10 of 72,000 pregnant patients at the Chicago Lying-in hospital,¹ the cases reported below are presented in detail.

The sedimentation rates mentioned in these cases were determined by the Wintrobe method, corrected for anemia, with normal results in women of up to 20 mm in 1 hour. Normal values for the icteric index were 4 to 7 units per cubic centimeter. In the bromsulfalein test 5 mg of dye per kilogram of body weight was employed, and 0 to 5 per cent retention of the dye in 30 minutes was considered normal. All hippuric acid excretion tests were based on the oral administration of 6 gm of sodium benzoate, the excretion of 3 gm of hippuric acid being regarded as 100 per cent, values as low as 80 per cent were considered normal.

CASE 1 A 26-year-old multipara, who had been followed in the hospital since the age of 10 for cretinism, secondary anemia and multiple nephrolithiasis, was admitted to the hospital on January 11, 1945. There had been no change in the kidney stones during recent years. The cretinism had been well controlled by desiccated thyroid and was stable, giving no problems during the interval covered by this report. The patient admitted a single sexual exposure in August, 1944, although she claimed continuation of the menses up to the time of admission. The expected delivery date was some time in May. On about December 11 she had suddenly developed anorexia, nausea, severe vomiting, constipation, lethargy, low-back pain, photophobia, excessive lacrimation and frontal headaches. Several days later she noted dark urine, light stools and the appearance of jaundice. A vaginal discharge also developed. All the symptoms disappeared after approximately 1 week, but the jaundice continued to be intense. There was no history of contact with infectious hepatitis.

Physical examination revealed deep jaundice, marked sluggishness, a uterus enlarged to the umbilicus and numerous vaginal polyps (identified by biopsy as condylomata acuminata). The liver and spleen were not palpated, and the temperature was normal.

Examination of the blood disclosed a red-cell count of 3,200,000, with a hemoglobin of 9.3 gm, and a white-cell count of 6500, with 30 per cent lymphocytes. The icteric index was 50, and there was an immediate direct van den Bergh reaction. Examination of the urine showed large amounts of bile and slightly increased amounts of urobilinogen. Blood Kahn and Hinton tests were negative. The hippuric acid excretion was 0. The principal tests by which the patient's course was followed are presented in Table 1.

Initial therapy consisted of a light diet, a single infusion of physiologic saline solution, complete bed rest and continued oral administration of desiccated thyroid, the dosage being adjusted from time to time on the basis of basal metabolic rates.

On January 15 a special diet, consisting of 150 gm of protein, 80 gm of fat and 200 gm of carbohydrate was begun, supplemented by 50 gm of casein hydrolysate (in the form of 1000 cc of Amigen solution) and 100 gm of glucose (as 1000 cc of 10 per cent glucose solution in distilled water) intravenously daily; 5 cc of crude liver extract and various synthetic components of the vitamin B complex were given intramuscularly daily and 20 gm of brewer's yeast with 60 cc of crude liver extract by mouth daily. Additional tests of liver function revealed the prothrombin time to be normal, the total protein was 5.1 gm per 100 cc, with 3.1 gm of albumin and 2.0 gm of globulin, and a quantitative indirect van den Bergh test showed increased amounts of hemobilirubin. An oral glucose-tolerance test on January 22 was normal.

There was a gradual fall in the icteric index and a diminution in the clinical signs of jaundice, although the sedimentation rate was unchanged. On February 5 the patient insisted on getting up daily, and the therapy was discontinued because of nausea and vomiting, which the patient attributed to the treatment. The appetite continued poor, so that little of the diet was actually taken. On February 8 and 10 she was given transfusions of 500 cc of blood, since the red-cell count and hemoglobin had fallen. Four days later the Amigen was resumed intravenously, with vitamin supplements and liver extract by mouth. The clinical condition and laboratory tests failed to improve further, and on March 2 a tender liver was palpated below the costal margin. With the lack of improvement, all treatment was stopped on March 5 for a period of observation, the bromsulfalein retention increased, the hippuric acid excretion further decreased, and the liver remained enlarged and tender. A glucose-tolerance test 10 days later showed a definite reduction in tolerance. There was constant anorexia and nausea, with vomiting that was occasionally severe enough to produce marked acetoneuria. Under these circumstances it was deemed necessary to terminate the pregnancy. On March 24 a cesarean section was performed under spinal anesthesia. The umbilical cord was green, and the amniotic fluid yellow, but the baby appeared normal. Seven days later the baby died. Autopsy showed no disease related to the maternal hepatitis, and death was attributed to atelectasis from aspirated gastric contents, pulmonary congestion and prematurity. The child's liver appeared normal.

Following the cesarean section the mother was given another transfusion and was again confined to bed. For several days she ran a high temperature, whose cause was never determined. Several blood cultures were negative. The temperature eventually returned to normal, and a steady improvement in the liver function tests, with a slow clinical improvement, began. On April 9 the patient was again allowed up. On April 23 she received another transfusion, and the glucose-tolerance test was normal. Clinical jaundice disappeared on April 30, but the liver was still enlarged. In an attempt to speed resolution of the enlargement the intravenous casein hydrolysate and intramuscular liver extract were resumed on May 7. On that day the total blood protein was 6.1 gm per 100 cc, with an albumin of 4.4 gm and a globulin of 1.7 gm. Treatment was stopped on May 17, which was the last day on which the liver was palpable. Two more transfusions were subsequently given. Finally, on May 26, being in excellent condition, the patient was discharged.

Subsequent visits showed continued well being, and the anemia improved, although the blood counts were still not within normal limits. On the last visit—in February, 1946—the blood sugar was 80 mg, and the total blood protein 6.3 gm per 100 cc. There was a change in the albumin-globulin ratio however, the former being 3.1 gm and the latter 3.2 gm.

*From the Department of Medicine, Maine General Hospital.

†Senior attending physician, Maine General Hospital.

‡Formerly resident physician, Maine General Hospital.

This patient contracted infectious hepatitis in the second trimester of pregnancy. Intense jaundice persisted, and there was evidence of liver damage. Following the start of therapy, there was some improvement over two months. When treatment was stopped there was evidence of further deterioration, and it was decided to interrupt the pregnancy. Cesarean section was performed at about the seventh month. The baby died from causes probably not associated with the hepatitis. After the section there was clinical and chemical improvement, which cannot be attributed specifically to any therapy given. Seven and a half months after discharge, there was still an elevated sedimentation rate and altered blood protein, some permanent liver damage presumably being indicated. The total period of jaundice was approximately one hundred and thirty days.

CASE 2. A 26-year-old woman who had had five previous normal pregnancies and births was admitted to the hospital on April 27, 1945. She had been seen in the hospital in 1943 for bronchiectasis and emphysema. The last menstrual period had begun in October 1944 and delivery was expected in July 1945. The pregnancy had been uneventful until April 22, when fever, low back ache, nausea, vomiting, anorexia and constipation had gradually begun. There was no history of contact with infectious hepatitis.

Physical examination showed a moderately ill patient, with a normal intrauterine pregnancy, coarse rales in both upper-lung fields, tenderness in the right upper quadrant of the abdomen and left costovertebral tenderness. She was treated with complete bed rest, a diet of soft foods and an occasional infusion when the vomiting was marked. Examination of the urine disclosed hile, albumin, sugar and casts.

On the next day clinical evidence of jaundice appeared. The sedimentation rate was 42 mm., and the icteric index 25 with an immediate direct van den Bergh reaction. The fever was of low grade, the temperature never exceeding 100°F. by mouth and together with most symptoms had disappeared by April 29. An x-ray film of the chest showed the same degree of fibrosis as previously, a urine culture was negative, and blood Kahn and Hinton tests were negative. Symptomatically the patient was well and since there were no clinical signs, she was followed solely by laboratory tests.

On April 30 the icteric index had risen to 40, the white-cell count was 7300 and the urine still showed bile, albumin and sugar. On May 1 the sedimentation rate was 32 mm. in 1 hour and the icteric index 52, and the bromsulfalein test showed 80 per cent retention of the dye. The diet was changed to 175 gm. of protein, 80 gm. of fat and 225 gm. of carbohydrate with about 15 gm. of brewers yeast daily. On May 7 the icteric index was still 50, the sedimentation rate had risen again to 33 mm. in 1 hour, the total blood protein was 6.4 gm. per 100 cc. with 3.0 gm. of albumin and 3.4 gm. of globulin and the stools were still clay colored. It was decided to reinforce the daily diet with 5 cc. of crude liver extract intramuscularly and 50 gm. of casein hydrolysate intravenously. At first these infusions gave many febrile reactions and further decreased the appetite but tolerance to them gradually improved.

On the morning of May 9 the patient passed blood clots by vagina and labor pains started. An easy delivery was performed 4 hours later. The pregnancy had thus progressed to approximately 6½ months. The child weighed 3 pounds 10½ ounces but appeared well. The baby was kept in the hospital until June 18, when the weight was 5 pounds 3 ounces and it was discharged in excellent condition.

Following delivery the patient was put on a regular diet but the Amigen, brewers yeast and liver extract were continued. On May 10 the sedimentation rate was 50 mm. in 1 hour, and the icteric index was 50. Thereafter she began to improve. On May 15 urobilin reappeared in the stools, the icteric index was 25, the blood cholesterol 214 mg. per 100 cc. and the sedimentation rate 46 mm. in 1 hour. Four

days later a hippuric acid test showed 30 per cent excretion but the bromsulfalein test revealed only 15 per cent retention of the dye. The icteric index was 20 on May 21 and 15 on May 24 and 31 by which time the sedimentation rate was 44 mm. in 1 hour, bilirubin had disappeared and the cholesterol was 188 mg. per 100 cc. On June 5 the icteric index was 10, and the sedimentation rate 44 mm. in 1 hour and the bromsulfalein test showed 15 per cent retention of the dye. The patient was then allowed up for the first time. Three days later the icteric index was 10, the sedimentation rate was 43

*Cesarean section performed on this date.

†Patient discharged.

mm. in 1 hour and the bromsulfalein test showed 10 per cent retention of the dye. The casein infusions, yeast and liver extract were discontinued. June 12 the liver function tests were normal — the hippuric acid test was 82 per cent and the bromsulfalein test showed 5 per cent retention of the dye, the icteric index was 10 and the sedimentation rate 47 mm. in 1 hour.

The patient was discharged on June 14 on a high-carbohydrate, high-protein diet. Two weeks later the icteric index was 5 and the sedimentation rate 31 mm. in 1 hour. She did not return for further follow up study.

This patient contracted hepatitis late in the second trimester of pregnancy, showed definite evidence of liver dysfunction, and was delivered at six and a half months of a normal baby who lived. Improvement began soon after delivery. Before discharge the patient showed a complete clinical recovery, all laboratory tests having returned to normal except for a high sedimentation rate. She did not return for follow-up studies, so that no statement can be made regarding permanent liver damage, although it seems unlikely. The jaundice lasted approximately thirty days.

CASE 3. A 24-year-old woman who had had a previous normal pregnancy was admitted to the hospital on May 23,

1945, with the complaint of jaundice. The last menstrual period had begun on December 1, and the expected date of confinement was September 7. On March 18 a dead but otherwise apparently normal fetus had been delivered at another hospital. On April 18 the patient had noted the gradual onset of nausea, vomiting, diarrhea and fever. There had been no known contact with hepatitis. Several days later the stools had become light in color, and the urine dark. Jaundice had then developed. She had not limited her activities or sought medical advice. The fever and symptoms had gradually disappeared, but the jaundice had become intenser and had shown no signs of remission.

Physical examination showed only the jaundice and a low-grade fever, the temperature never exceeding 100°F by mouth. Examination of the blood disclosed a white-cell count of 5500, with 37 per cent lymphocytes. The icteric index was 100, with an immediate direct van den Bergh reaction, the sedimentation rate was 5 mm in 1 hour, a bromsulfalein test showed 100 per cent retention of the dye, the blood cholesterol was 137 mg per 100 cc, and blood Kahn and Hinton tests were negative. Examination of the urine disclosed heavy amounts of bile with traces of sugar. The stools were definitely light in color.

The patient was immediately put on complete bed rest and started on a high-protein diet. On May 25 daily administration of 1000 cc of Amigen solution intravenously, 10 gm of yeast and vitamin supplements by mouth and 5 cc of crude liver extract intramuscularly was begun. Because of the poor condition of the veins, it was not always possible to give the daily infusion. The fever soon disappeared, and since the patient had no symptoms or physical signs, the course was followed solely by the laboratory tests.

On May 31 the icteric index had risen to 150, the sedimentation rate was 10 mm in 1 hour, the bromsulfalein retention was still complete, and a Takata-Ara flocculation test was negative. On June 5 there was no fundamental change, the icteric index being 100 and the sedimentation rate 21 mm in 1 hour. A week later the icteric index was the same, the cholesterol was 188 mg, and the blood protein 6.1 gm per 100 cc, with 4.4 gm of albumin and 1.7 gm of globulin. On June 18 the icteric index fell below the admission level for the first time, being 75, and the sedimentation rate was 18 mm in 1 hour. Amigen infusions were discontinued after 30 days. On June 26 and July 3 the icteric index was the same, there was still an immediate direct van den Bergh reaction and a sedimentation rate of 20 mm in 1 hour, but on the latter date the bromsulfalein test showed 40 per cent retention of the dye. On that day the patient was allowed up for the first time. The yeast, vitamins and liver extract were continued. A week later the icteric index was 50. She went home July 13 and probably took no medications or diet. The jaundice, however, disappeared soon after discharge.

The icteric index was 15 on July 18 and 10 on August 1, when the bromsulfalein test showed 15 per cent retention of the dye. Further bromsulfalein tests showed 20 per cent retention on September 13, none on October 24 and none on January 4, 1946.

This case might strictly be excluded from the series, since symptoms of hepatitis first appeared about thirty-one days after a miscarriage, occurring at the end of the first trimester. Since Havens² has stated that the incubation period is from twenty to forty days, however, it is evident that infection occurred at about the time of, or perhaps even before, the miscarriage. Whether the hepatitis was directly related to the miscarriage cannot, of course, be determined. After a month of jaundice, therapy was started. Although treatment was not so intensive as we should have wished, some improvement began about three weeks after admission and continued until no evidence of liver damage was apparent. The total duration of jaundice was eighty to eighty-five days.

CASE 4 A 39-year-old woman who had had a tubal pregnancy in 1932 and five subsequent normal pregnancies was admitted to the hospital on June 1, 1945, acutely ill. The last menstrual period had begun on November 23, and the expected date of delivery was August 30. On May 30 she had had a shaking chill and had rapidly developed fever, sweating, headache, nausea, vomiting, severe pains in the lower back and lower abdomen and pain on moving the eyes.

Physical examination showed only a normal intrauterine pregnancy. On the next day examination of the blood revealed a red-cell count of 3,300,000, with a hemoglobin of 11 gm, and a white-cell count of 3200, with 15 per cent lymphocytes. The icteric index was 5, and a bromsulfalein test showed 70 per cent retention of the dye. The urine was normal. No history of contact with hepatitis could be obtained.

The symptoms and a low-grade fever persisted until June 4, when clay-colored stools and bilirubin developed. On the following day jaundice appeared. On June 6 the icteric index was 50 with an immediate direct van den Bergh reaction, and the sedimentation rate was 18 mm in 1 hour. Treatment consisted of complete bed rest, codeine for the headache and backache and 2000 to 3000 cc of 10 per cent glucose solution in distilled water by vein daily. By June 8 the patient felt well enough to start on a normal diet, the codeine and infusions being discontinued. On the next day the icteric index was still 50, and the sedimentation rate had risen to 32 mm in 1 hour. On June 11 an enlarged tender liver was palpated. An oral glucose-tolerance test was normal on the following day. On June 15 the bromsulfalein test disclosed 40 per cent retention of the dye, a quantitative indirect van den Bergh test showed 5 mg of hemobilirubin per 100 cc, and the sedimentation rate was 46 mm in 1 hour. Eight days later the icteric index was 15, and the sedimentation rate 37 mm in 1 hour, and the bromsulfalein test revealed 20 per cent retention of the dye. The liver gradually diminished in size until June 27, when it could no longer be felt, all jaundice had gone, the icteric index was down to 10, the bromsulfalein retention was only 5 per cent, and the sedimentation rate was 27 mm in 1 hour. The patient was allowed up on that day. On July 2 the icterus was the same, and the sedimentation rate 38 mm in 1 hour. She was discharged two days later.

The patient was not seen again until September 13, when she entered the hospital and spontaneously delivered a normal child. Unfortunately, no liver-function tests were done at that time. The hospital course was uneventful for both the mother and the child.

Four months later the patient was in perfect health, and the liver could not be palpated. The icteric index was 7.5, a van den Bergh test gave no reaction, the sedimentation rate was 9 mm in 1 hour, the Takata-Ara reaction was negative, and a bromsulfalein test showed no retention of the dye.

There is remarkably little in the literature on the concurrence of infectious hepatitis and pregnancy, to which Beck³ refers as catarrhal jaundice, a condition that is seldom seen in pregnancy. De Lee¹ states that pregnant women show a high mortality in hepatitis. Stander⁴ considered "the catarrhal variety" of jaundice in pregnancy to be without significance and to undergo spontaneous cure, but subsequently referred to "epidemics of jaundice in which the disease was disastrous in pregnancy."⁵ In the latter report there were many maternal deaths, abortions and premature deliveries.

Saurer⁶ reported 5 cases of hepatitis in pregnant women occurring during 1942 and 1943. Four were multiparas ranging in age from twenty-four to thirty-seven years. One had a premature delivery at five months and later developed symptoms of hepatitis, as in Case 3 above. This was apparently the only premature delivery. There were no maternal deaths and no other fetal deaths. Only one

woman, who had delivered at term during the preicteric stage of hepatitis, had a prolonged period of jaundice. In this case the jaundice lasted about three months.

It is impossible to draw definite conclusions from our small series of cases. There were no maternal deaths, and the 2 deaths in the children could be attributed only to the prematurity, not to the maternal hepatitis. In only one woman, however, did both the pregnancy and the hepatitis pursue normal courses. Two patients had premature labors, 1 required termination of the pregnancy, and 2 had prolonged periods of jaundice. The patient in Case 1 may have suffered permanent liver damage, since when last seen she still had an elevated sedimentation rate and an abnormal blood protein level. Permanent damage seems definitely ruled out in Case 4 and unlikely in the other 2 cases.

It seems safe to conclude that the danger of maternal death from hepatitis is small. The chance of an uneventful pregnancy is poor, however, and the possibility of prolonged jaundice and perhaps permanent liver damage in the mother is present. Since improvement in the mother occurred soon after the cesarean section in Case 1 and soon after delivery in Case 2, it appears that the mother benefits from removal of the fetus. Pregnancy itself may place an extra strain on an already diseased liver, and in severe cases of hepatitis interruption of the pregnancy should be seriously considered unless the patient improves rapidly under observation.

Little other treatment will benefit, since therapy in infectious hepatitis has always been purely symptomatic. Recent work by Gellis et al.⁷ and by Stokes and Neefe⁸ has proved the value of the early prophylactic use of gamma globulin, but the therapy is of no apparent value once symptoms have developed. It might be wise to give a prophylactic dose immediately to every pregnant woman exposed to hepatitis. The difficulty, however, is that in most cases, as in all those presented above, there is no history of known exposure. In the absence of such a history, prompt hospitalization, with complete bed rest, is recommended as soon as the diagnosis of infectious hepatitis is made or suspected in a pregnant woman. Of all the therapy used, bed rest is probably the most important factor. Proof for this statement is not apparent in these 4 cases, but in a large series of uncomplicated cases of hepatitis the duration of jaundice was found to be inversely proportional to the amount of strict bed rest instituted at the onset of the disease, being 40 per cent less in patients hospitalized early than in those whose activity had not been restricted. The 2 patients in this series who were put to bed during the preicteric stage of the disease were jaundiced for only twenty-one and thirty days, respectively,

whereas the other 2, who did not limit their activity, were icteric for eighty and one hundred and thirty days, respectively.

The remainder of the treatment fundamentally consisted in furnishing large amounts of protein, carbohydrate and vitamins in the diet, while limiting the amount of fat. Because of the marked gastrointestinal symptoms the diet was often poorly taken and was therefore supplemented with infusions of glucose and casein hydrolysate, liver extract intramuscularly and yeast and vitamin supplements by mouth. Variations of this therapy were used in 3 cases, with indefinite results. Case 1, after jaundice for a month, showed improvement starting after about two weeks of this treatment. The improvement, however, was not complete since the liver became enlarged, although when treatment was stopped liver function was further impaired. In Case 2 delivery occurred a few days after this regime had been instituted, so that the rapid improvement thereafter may be attributed to either factor. One patient (Case 3) had been jaundiced for a month and began to improve after three weeks of this routine, going on to complete recovery.

From our limited experience, we suggest that gamma globulin be promptly given to a pregnant woman exposed to hepatitis, or if an epidemic has started. Otherwise, the patient should be hospitalized immediately when symptoms develop and given complete bed rest. Then, if the jaundice does not diminish within a few weeks or if the patient had already been jaundiced for some time before hospitalization, the above regime is recommended.

SUMMARY

Four cases of infectious hepatitis occurring in pregnant women are described. Two women had premature deliveries, and a third required interruption of the pregnancy. Two women had markedly prolonged periods of jaundice that in 1 resulted perhaps in permanent liver damage.

A suggested outline for management of such cases is presented.

MECKEL'S DIVERTICULUM*

Report of Two Unusual Cases

WILLIAM R. MOSES, M.D.†

WASHINGTON, D. C.

ALTHOUGH Meckel¹ is usually credited with the first descriptions of the diverticulum in 1812, Hildanus² first mentioned the lesion in 1598, Lavater³ described it again forty years before Meckel, and Ruysch⁴ presented a complete description in 1701. Deneke⁵ reported the first clinical case of ulcer in the diverticulum. Deetz⁶ originally demonstrated gastric tissue in the mucosa. Heterotopic pancreatic tissue was first noted by Zenker.⁷ Womack⁸ credits Tillmans with the first demonstration of hydrochloric acid secretion by the gastric glands in the diverticulum.

Incidence

The incidence of Meckel's diverticulum is generally accepted to be in the neighborhood of 2 per cent of the population, an estimate concurred in by Nygaard and Walters,⁹ Skinner and Walters,¹⁰ Gray,¹¹ Abt and Strauss,¹² Chaffin,¹³ Osler¹⁴ and Turner.¹⁵ Other estimates include that of Ladd¹⁶ (2 to 4 per cent), that of Matt and Timpone¹⁷ (15 to 30 per cent) and that of Christie¹⁸ (11 per cent).

There is consistent agreement among authors that the lesion is a cause of clinical disease in from 15 to 25 per cent of patients in whom it occurs.^{1, 9, 18-21} Since this estimate implies that approximately 1 person in each 200 of the general population would be so afflicted, there seems reason to believe that the estimate is too high. During the past five years at this hospital there have been 26 known cases of lesions of the diverticulum, 631 cases of appendicitis having been seen in the same period. Thus, our experience demonstrates that appendicitis is twenty-five times more frequent.

Anatomy

The origin of the pouch is the failure of closure of the omphalomesenteric duct, which normally occurs by the seventh fetal week. The sac is usually found on the antimesenteric border of the ileum and rarely between the leaves of the mesentery. It has been found, however, arising from all parts of the intestinal canal from the cardia of the stomach to the rectum. The distance separating it from the ileocecal valve is usually 30 to 90 cm. The sac is often under 10 cm in length and averages about the size of a finger. There have been several

reports of "giant" forms, the largest being that described by Tisdall,²² which was over 100 cm long, that of Chaffin,¹³ which was 96 cm long, that of Moll,²³ which was 85 cm long, and that of Goldstein,²⁴ which was 66 cm long.

Pathology

Anatomic derangements of the structure that may occur are classified by Thompson²⁵ as follows: antimesenteric, with closed distal end, 82.5 per cent, partial obliteration, with a fibrous cord running to the umbilicus, 10 per cent, umbilical fistula, 6 per cent, "giant" forms, 5 per cent, umbilical polyp, 0.5 per cent, and simple intramesenteric, 0.5 per cent.

Sibley²⁶ has listed the following structural peculiarities of the lesion: persistence of lumen in the vitelline duct resulting in fistula to the umbilicus, obliteration of the lumen of the cord, with attachment of the cord to the navel, to other viscera or without attachment, cyst formation in the cord, the cyst being either central or distal, with formation of an umbilical sinus, formation of a blind, free-lying pouch — the usual variety, a "daughter" diverticulum arising from the original sac, a blind pouch lying between the leaves of the mesentery, and segmental obliteration, but with persistence of mucosa-lined duct in other areas, communicating with the navel or other viscera.

The study of heterotopic tissue in the diverticulum is one of the most interesting pathologic features encountered. This sac is easily the most frequent site for observance of heterotopic tissue, the incidence of the phenomenon being 34.9 per cent in a total of 1044 cases reviewed^{17, 27-36} and the type of tissue noted being gastric, duodenal and jejunal mucosa, pancreatic tissue and biliary duct.

At present there are three theories in explanation of the presence of heterotopic tissue in the diverticulum. The Albrecht³⁷ theory holds that the sac contains primitive endoderm that can reproduce any cells of the gastrointestinal tract, in contrast to the Schaetz³¹ theory, which explains the ectopic cells by implantation during rotation of the gut. Greenblatt²¹ favors the "dysembryoma" theory, which considers the diverticulum as a primitive digestive tract and accounts for the heterotopic cells by their failure to undergo involution, a view adhered to by Farr and Penke.³²

Of the multiplicity of types observed, only the gastric cells are encountered with any frequency,

*From the Surgical Service, Gallinger Municipal Hospital.

†Adjunct clinical professor of surgery, George Washington University School of Medicine.

and only they have any apparent clinical significance, owing to their ability to form peptic ulcers in the contiguous tissues. Schaaft¹⁶ analyzed the fluid formed by such a diverticulum and demonstrated a free hydrochloric acidity of 40° and a total acidity of 70°. Dragstedt,¹⁹ Lundau and Wulff²⁰ and Matthews and Dragstedt²¹ have shown that this lesion is analogous to the peptic ulcer of the upper intestinal tract, representing a lack of resistance of ileal mucosa to acid contact. It is of interest that the ulcer occurs, not in the patch of gastric cells, but usually in the junction zone of gastric and ileal tissue, often growing to an appreciable extent along the ileal mucosa.

The clinical syndromes that may occur as a result of a lesion in the diverticulum have been classified by Greenblatt and his associates²² as follows:

The peptic group, a common feature of which is the presence of heterotopic gastric mucosa in the sac, which may or may not cause a peptic ulcer that may in turn cause intestinal hemorrhage or peritonitis by perforation. The patient may thus present the clinical picture of a simple duodenal ulcer, melena, hematemesis or peritonitis.

The obstructive group, in which the pouch is the focus of intussusception, a volvulus, the contents of an inguinal or femoral hernia (Littre's hernia), or the cause of bands and adhesions. The clinical picture is then one of complete or incomplete, acute or chronic intestinal obstruction.

The diverticular group, in which the sac is subject to acute or chronic inflammation, with the possibility of gangrenous change, and in which the symptomatology is essentially that of appendicitis.

The umbilical group, presenting as a fecal fistula, umbilical adenoma or prolapse of intestine through an umbilical fistula.

The tumor group, either benign (enterocystoma, carcinoid, adenoma or mesodermal tumor) or malignant (carcinoma or sarcoma).

The incidental group, in which the lesion occurs without symptoms.

Complications and Symptoms

A collective review of the cases reported and reviewed by forty-three authors reveals various complications reported among 1605 cases (Table 1).

The most frequent complication encountered is hemorrhage from the diverticulum, which invariably results from either peptic ulceration or neoplasm. The complication is two to five times as common in boys as in girls^{23, 24, 25} and is usually seen in the group from ten to twenty years of age,¹⁷ 74 per cent of cases occurring under the age of fifteen years,¹⁸ but has been encountered at operation in an age span from two weeks to seventy-seven years.²¹

The bleeding may be slight, periodic or intermittent or sudden and profuse, the blood is usually dark rather than either bright or tarry. If the hemorrhage is associated with pain, the distress is usually umbilical in location and may be accentuated, but not relieved, by food.²⁶ Matt and Timponi¹⁷ state that there are usually long intervals separating episodes of massive melena, which may continue into adult life, and that such a history is almost pathognomonic of a diverticular ulcer. The differential diagnosis includes intussusception (as indicated by "raspberry jam" stools with obstructive symp-

TABLE 1 Complications Observed in 1605 Cases of Meckel's Diverticulum

COMPLICATION	NO. OF CASES	PERCENTAGE
Hemorrhage	496	30.9
Intestinal obstruction	383	23.8

Prolapse through navel	6	0.37
Omphalocele	3	0.18
Traumatic perforation	3	0.18

toms), Henoch's purpura (on the basis of purpuric spots and studies of platelet counts, clot retraction, and clotting and bleeding times), peptic ulcer (as suggested by the patient's age, epigastric pain, response to alkalis and barium studies), colonic and rectal polyps (as indicated by tenesmus, proctoscopy and barium enema), rectal varicosities (visible on proctoscopy) and congenital intestinal telangiectasis. Brenneman²⁷ has observed that the rectal blood from a Meckel's diverticulum usually contains clots, whereas that formed by an intussusception or an ileocolitis usually does not.

Intestinal obstruction, which is second to hemorrhage in frequency as a complication, generally results from intussusception, with the pouch forming the head of the advancing loop, from volvulus, from bands and adhesions arising from previous inflammatory changes around the sac or from congenital attachments. According to Harkins,²⁸ intussusception accounts for 17 per cent of the complications arising in Meckel's diverticulum. Precise diagnosis of the cause of the obstruction prior to operation in such cases is manifestly impossible, unless the characteristic antecedent history is present.

Perforation is the third most frequent complication mentioned in the literature and may result from either perforation of a peptic ulcer or advanced diverticulitis. Unless there has been a

history of melena, it will be impossible to differentiate the condition from appendicitis with perforation.

The finding of a diverticulum in a hernial sac is known as a Littre's hernia, and the occurrence may or may not be associated with the syndrome of intestinal obstruction. The relatively large number of cases reported lends a false impression of its frequency, and probably represents the desire of authors to report the bizarre rather than the more usual lesions. In 1943 Bird⁴⁹ collected 182 cases, of which 52 per cent were inguinal, 20 per cent femoral and 20 per cent umbilical.

Simple diverticulitis is actually more frequent than the literature suggests, its apparent rarity probably being due to its prosaic nature. Peritonitis following gangrene with perforation has occurred during intrauterine life. Stewart⁵⁰ states that the clinical picture is pathognomonic if there is localized tenderness on the right side just above McBurney's point at the level of the umbilicus. Wolfson and Clurman⁵¹ attempt to differentiate appendicitis from diverticulitis by the severer and more colicky pain, greater distention and more pronounced vomiting accompanying the former. Despite these observations most clinicians are not so sanguine of their ability to differentiate the two conditions.

Foreign bodies found in these sacs include fish bones, gallstones, marbles and bullets.

Malignant tumors involving the diverticulum are rare, about 24 cases having been reported. Nygaard and Walters,⁹ and Skinner and Walters¹⁰ have collected 16 cases of sarcoma and 6 of carcinoma, to which group Albright and Sprague³³ have added another case of carcinoma. In 5 cases the tumors were clinically palpable before laparotomy. It is of interest that in 6 cases the lesions were demonstrated by barium studies of the small bowel.

In general, barium studies have been disappointing in demonstrating the sac. In 1943 Rousseau and Martin⁵² reported a total of 13 cases in which diagnosis was made before operation. Tracey and Adams⁵³ and Carlson⁵⁴ have since reported individual cases. Albright and Sprague³³ advise the use of hourly films during the first five hours after ingestion of the barium meal to increase the radiologic accuracy of diagnosis.

Treatment

The usual management at operation consists in excision with burial of the stump, as in appendectomy. Matt and Timpone,¹⁷ however, strongly recommend resection of the contiguous ileum with primary anastomosis because of the known tendency of heterotopic tissue in the pouch to grow beyond the neck into the neighboring bowel. Perhaps a rational plan would be to use the simple and relatively safer appendiceal technic in the treatment of inflammatory lesions in which the frequency and importance of aberrant tissue is less, and to reserve

the ileal resection for cases with bleeding, in which heterotopic cells are certain to exist. Obviously, the patient's general condition, the size of the neck of the sac and other factors will influence this generalization.

The two following cases are reported because of their unusual complications, one of which is, to the best of my knowledge, recorded for the first time.

CASE 1 (B91258) C B, a 48-year-old Negress, was admitted to the hospital on July 26, 1944, with the complaint of intermittent swelling of the abdomen for 1 month, associated with moderate constipation and total absence of stool or flatus for 3 days. Nausea had been intermittent, but without vomiting. There had been no change in the color of the stools. Five months before admission, in another hospital, a diagnosis of congestive failure due to hypertension had been made, and the patient had been subjected to thoracenteses on the right side twice during her stay. After 2 months she had been discharged on maintenance doses of digitalis and had noted on occasions moderate dyspnea, orthopnea and ankle edema. A hysterectomy for a "fibroid tumor" had been performed at the age of 16.

Dyspnea and orthopnea were striking features, and the patient appeared moderately toxic. The head and neck revealed no significant abnormalities other than markedly engorged neck veins. The heart appeared slightly enlarged, and a harsh mitral systolic murmur was heard. There was impaired resonance over the right lower-lung field, with diminution of breath and voice sounds. Basal rales of the subcrepitant variety were heard on the left. The abdomen, which was quite distended and exquisitely tender throughout, demonstrated a fluid wave and shifting dullness. Peristalsis seemed hyperactive. A well healed lower midline incision was visible. Examination of the rectum, vagina and extremities was negative.

The rectal temperature was 98.9°F, the pulse 84 and regular, and the respirations 32 and labored. The blood pressure was 114/64 in both arms.

Examination of the blood disclosed a red-cell count of 2,630,000, with a hemoglobin of 40 per cent (Sahli), and a white-cell count of 10,600, with a normal differential. The urine was normal. A blood Kahn test was negative. The icteric index was 25, and the van den Bergh reaction indirect. The blood urea nitrogen was 11 mg and the total protein 5.4 gm per 100 cc, with an albumin of 2.6 gm and a globulin of 2.8 gm. The urine was positive for urobilinogen in a 1:10 dilution, the guaiac reaction of the stools varied from negative to + + + +, but there was no gross blood. An electrocardiogram revealed strain of the left ventricle. X-ray films of the chest showed a thickened pleura at the right base and enlargement of the cardiac silhouette, with a hypertensive outline. Films of the abdomen disclosed fluid levels in the small bowel on repeated examinations.

The succeeding 20 days were marked by febrile rises to 101 to 102°F by rectum, bouts of distention relieved by insertion of a Miller-Abbott tube, episodes of clinical shock, diarrhea on occasions and absence of gross fecal blood. The usual therapeutic measures for cardiac failure were administered, and repeated transfusions of blood and plasma were given. On two occasions blood aspirated from the peritoneal cavity failed to clot on standing. On August 16 a laparotomy was performed under ethylene and ether anesthesia.

After celiotomy through a rectus incision approximately 3000 cc of blood was found in the peritoneal cavity. A diverticular mass, spherical in outline and 12 cm in diameter, was seen arising from the terminal ileum, about 45 cm from the ileocecal valve, it was firmly adherent to other loops of small bowel, the ascending and transverse colon and the right lateral and anterior abdominal walls. A slow ooze of dark blood was noted from a small hole in the base of the mass near its junction with the ileum. Resection of the diverticulum with a segment of the corresponding ileum, with primary anastomosis of the ileum, was performed.

The postoperative course was not remarkable, and the patient left the hospital in good condition on the 27th postoperative day.

Pathological examination revealed a 3 mm perforation in the base of the diverticulum and a communication with the ileum just large enough to admit a small probe, the entire mucosal lining was ulcerated and hemorrhagic, and the lumen was filled with liquid and clotted blood.

This case demonstrates a massive peptic ulcer in a Meckel's diverticulum, with perforation into the peritoneal cavity, hemoperitoneum and intestinal obstruction. This appears to be the first case with free bleeding into the abdominal cavity. Chaffin¹³ reported a case with hemoperitoneum in which the blood was the result of a torn adhesion. There is a striking similarity between the case reported above and a case of gastric diverticulum associated with hemoperitoneum previously reported.¹⁴

CASE 2 (C17811) W. C., a 53 year-old man was admitted to the hospital on November 29, 1945, with a history of weakness and faintness of 2 weeks' duration following the passage of several "purple" stools whose color he interpreted as bloody. Two days later the color of the stools had returned to normal. The patient had been placed on a Sippy regime by a physician during this period. Two years prior to this episode he had experienced a similar attack and had been told that he had a peptic ulcer. He had received several transfusions at another hospital but had never had the clinical diagnosis confirmed by barium studies. He had never had pain at any time or bleeding from other areas of the body.

Physical examination revealed no abnormalities other than general pallor.

Examination of the blood disclosed a red-cell count of 2,170,000 with a hemoglobin of 51 per cent (Sahli) and a white-cell count of 4,770, with a normal differential. The blood Kahn test was negative. The total protein was 5.5 gm per 100 cc. The bleeding, clotting and prothrombin times were normal, and the tourniquet test negative. Analysis revealed a low gastric acid. The stools were consistently negative for occult blood, ova and parasites. Repeated barium enemas and barium meals failed to demonstrate any lesion of the intestinal tract. There was no recurrence of bleeding at any time during the 7 weeks' stay. Repeated proctoscopic examinations failed to demonstrate any lesion of the rectum or sigmoid.

After repeated transfusions the patient was discharged in excellent condition and advised to return promptly if bleeding recurred. The diagnoses mentioned as most probable at time of discharge were Meckel's diverticulum and intestinal polyp. Not the failure of confirmation of melena during hospitalization was considered justification for conservative management.

The patient was readmitted on June 13, 1946. He stated that he had had a sudden and severe pain in the right lower quadrant beginning 3 days previously and that this pain had been constant in duration and quality, followed by vomiting on the day before admission. There had been no interval changes in stool color or habits.

On physical examination the patient did not appear acutely ill, the salient findings being confined to the abdomen which demonstrated marked tenderness in the area of McBurney's point, local rigidity, rebound tenderness, pain on coughing and absent peristaltic sounds.

The rectal temperature was 101.8°F, the pulse 80, and the respirations 20. The blood pressure was 104/64.

Examination of the blood disclosed a red-cell count of 4,500,000 with a hemoglobin of 84 per cent (Sahli) and a white-cell count of 15,000 with 79 per cent granulocytes.

A positive diagnosis of Meckel's diverticulum was made, and an immediate laparotomy under spinal anesthesia was performed through a rectus incision. No free pus was encountered. An inflammatory diverticular mass communicating with two loops of the ileum was resected with involved sections of both loops of small bowel intestinal continuity being restored in each loop by end-to-end anastomoses. The convalescence was uncomplicated, and the patient was discharged in excellent condition on the 27th postoperative day.

Pathological examination of the specimen revealed a Meckel's diverticulum, which had established a fistula be-

tween itself and a higher loop of the ileum measured 11 by 8 by 5 cm and had undergone malignant degeneration with formation of a leiomyosarcoma. There were no evident metastases in the mesentery of the resected bowel nor had any metastases been noted at the time of laparotomy.

This case represents the seventeenth known case of sarcoma arising in a Meckel's diverticulum. It demonstrates the difficulty of diagnosis of this condition in adults and lends weight to the contention that cases of obscure intestinal bleeding should have laparotomies to establish the diagnosis when necessary.

SUMMARY

The history, incidence, anatomy, pathology, complications and symptoms of Meckel's diverticulum are reviewed, and a plan of therapy for the complications is offered.

Two case reports illustrating rare complications are presented, one of which is the seventeenth case of sarcoma arising in a Meckel's diverticulum, and the other the first case reported in which a peptic ulcer that had developed within such a diverticulum had bled into the peritoneal cavity.

ELECTROENCEPHALOGRAMS IN NEUROPSYCHIATRIC DISORDERS AMONG SOLDIERS

Results in 950 Cases

MILTON H. KIBBE, M.D.*

SPRINGFIELD, MASSACHUSETTS

IT WAS not until the latter months of 1943 and early 1944 that the Army made any extensive use of the electroencephalograph. By the middle of 1945 thirty-five brain-wave machines had been installed in different Army general hospitals throughout the United States. Six electroencephalographs were in use in overseas hospitals, and one overseas unit was completely mobile so that it could be taken to combat echelons for early study of cerebral injuries resulting from blast. The electroencephalograph adopted by the Army was the Grass machine of four or six channel type¹.

Although the Army was late in developing adequate electroencephalographic departments, there is no doubt that important and interesting data have been accumulated and should enhance the knowledge, understanding and appreciation of the value or limitations of the brain waves. It is with the purpose of adding to the understanding and interpretation of electroencephalograms that the results of 1470 electroencephalograms on various neuropsychiatric disorders among 950 soldiers are briefly presented.

The material for this report was gathered and interpreted almost exclusively by me on patients at

the Cushing General Hospital from August 1, 1944, to January 1, 1946. The disorders studied included open and closed head injuries, almost all types of epilepsies or related conditions, brain tumors, headaches of undetermined origin, migraine, cerebrovascular accidents, psychoneuroses, psychoses and miscellaneous disorders, such as encephalitis, meningitis and trigeminal neuralgia. The patients with head injuries were subdivided into those having open, compound fractures of the skull without penetration of the dura or brain, those with open wounds with penetration of the dura and brain and those with closed injuries without open or penetrating brain injuries. Cases of cephalalgia comprised all patients with headaches of undetermined origin but none who gave a typical history of hemiparesis or migraine, since these were tested as a separate group. The psychoneurotic group included a few cases of constitutional psychopathic personalities but no cases with a definite history of head injury of recent origin.

Head injuries were predominant in this series because a special head-injury section had been established in the neurologic and neurosurgical services of the hospital. The vast majority of these patients were received either from overseas via debarkation hospitals or from other Army hospitals

*Formerly, assistant chief, Neurological Section, Cushing General Hospital, Framingham, Massachusetts

in the Zone of the Interior from three to eight weeks after injury. A special study in selected cases of head injuries of the electroencephalographic findings, spinal-fluid analysis, post-traumatic seizures, neurologic and psychologic findings will be made available in a later paper.

All electroencephalograms were recorded from a four-channel Grass electroencephalograph. The brain waves were taken with the patient comfortably relaxed with eyes closed, on an easy chair in a properly shielded, grounded and darkened cage. Only strictly bed patients were examined lying down since artefacts frequently occurred if the subject was allowed to lie on the occipital electrodes, and the chances of obtaining sleep patterns in the records were greater in the reclining position. The standard type of lead-pellet electrode, with a small indentation for electrode paste, was used in all cases. In the method of applying electrodes, the time of recording from each area and the period of hyperventilation, the standards of operation set down by a War Department bulletin² was followed as closely as possible except that electrode placement had to be adapted to correspond to the cranial defect or area of injury and to compare this area as accurately as possible with the uninjured side.

Both monopolar and bipolar recordings were made except on the patients in whom localization was considered to be of no value. A specially designed rubber stamp of the position of all electrodes was placed on each record to determine accurately the point of greatest damage of intracranial lesions. Also, this diagram was found to be an excellent guide for placement of electrodes in subsequent electroencephalograms on the same patient. Odd numbers were used to designate left sided leads and even numbers for all right-sided leads. Most of the electrode placements and recordings were done by the same technician, who had been thoroughly and adequately trained at the School for Electroencephalographers of the Walter Reed General Hospital. Such consistency and uniformity in the placement of electrodes and methods of recording of brain waves is extremely important in the detection or elimination of artefacts and in comparing the tracings with previous records on the same patients.

The majority of the patients with open or penetrating wounds of the skull or brain had at least two electroencephalograms — one as soon as possible after admission to the hospital, and the other about two weeks after insertion of a skull plate or other operative procedure. A third or even fourth brain wave was frequently obtained just before the patient was discharged from the hospital. It was found that the presence of a tantalum plate in the skull (about 50 per cent of the open head injuries in this series) had no effect on the recording of electrical discharges from the brain. In patients with minor nonpenetrating brain injuries, psychoneuroses or

cephalalgias who showed normal tracings the electroencephalograms were not repeated, all borderline or abnormal records, however, were repeated if possible, and these records were carefully compared with previous ones. If typical Jacksonian seizures developed and the electroencephalograms repeatedly showed focal spike-wave discharges, the patient was presented to the neurosurgeon for possible cortical-scar resection.

Almost all the patients with head injuries who were found to have grossly dysrhythmic or focal records were placed on 0.032 gm of phenobarbital three times a day, and if convulsive seizures developed, this dosage was increased and perhaps Dilantin Sodium was also added. In this series of cases small or moderate doses of anticonvulsive drugs seemed to have no effect on the electroencephalograms and were not withheld before records were taken. This finding has also been confirmed in a recent survey.³

As indicated above practically all the electroencephalograms in this series were interpreted by me. This analysis consisted of an inspection of the entire record, the presence or absence of a dominant alpha frequency being noted. The amount and localization of any frequencies that were slower or faster than normal, the presence of paroxysmal discharges and the symmetry of the two hemispheres were carefully noted on the face sheet of each record. Any build-up after two or three minutes of hyperventilation was also noted. If any abnormality was seen, the tracing was studied in more detail and compared with previous electroencephalograms on the same patient. Sample cuts of any abnormal activity were taken from the record and mounted in folders that had been made for each case and contained, besides the sample brain wave, a clinical abstract of the patient, a copy of all operative procedures, psychologic data and photographs of any skull defects, intracranial foreign bodies and so forth.

Table 1 presents the results in the entire series. Of the 1470 electroencephalograms interpreted 32 per cent were normal, 16 per cent borderline, and 52 per cent abnormal. The results of the findings in the patients with head injuries are discussed below. The patients with epilepsy and related disorders included those in whom a history of some type of convulsive disorder was given, but this was not always proved by clinical observation. This fact probably explains the rather high incidence of normal or borderline records in this group. Of the 130 electroencephalograms showing definite cerebral dysrhythmia 77 were of the grand-mal pattern, 25 revealed petit-mal activity, 12 disclosed psychomotor seizures, 15 were probably best classified as demonstrating mixed types of seizure and 1 showed typical sleep spindles in a patient with narcolepsy.

A brain tumor was suspected in 23 patients, and 33 electroencephalographic tests were done on these subjects. Fifty-five per cent of the records were

definitely abnormal, and 37 per cent showed focal discharges, the underlying lesion being confirmed at operation in all cases. The 37 records of patients with headaches of unknown cause showed 68 per cent normal, 17 per cent borderline and 15 per cent abnormal. Migraine cases, however, yielded abnormal records in 33 per cent. The abnormality seen in the migraine tracings was, in most cases, generalized dysrhythmia, and this brings up again the interesting question whether migraine is related,

5 tested because of trigeminal neuralgia showed an abnormal record. The over-all incidence of abnormality in this group was 18 per cent. The abnormal records in the head-injury series were further classified as being generalized dysrhythmia if the record showed no focus of slow, fast or spike waves. Slow-wave foci were designated according to frequency as Grade I, or frequencies of 5 to 7.5 per second, Grade II, or 2 to 5 per second, and Grade III, or 0.5 to 2 per second. Foci of spike

electroencephalographically at least, to the convulsive disorders. Cerebrovascular accidents included cases of thromboses or hemorrhages, few of these cases, however, were of recent origin, and this fact probably explains why not more than 40 per cent of the

or fast waves were noted to be either continuous or paroxysmal. Table 2 presents the breakdown of the various types of head injuries according to this classification. From this analysis it will be noted that the slow-wave focus Grades II and III (frequencies of 0.5

electroencephalograms were abnormal. Only 6 per cent of the psychoneurotic records were abnormal, and since even so-called "normal subjects" show as many or even more abnormal patterns, it was believed that an abnormal electroencephalogram in this group was without much significance. On the other hand the 28 electroencephalograms of psychotic patients revealed an abnormality of 16 per cent, and 14 per cent were borderline. The miscellaneous group included 3 records of patients with a postmeningitic syndrome, which were abnormal, and 2 of patients following encephalitis, which were dysrhythmic. One case of the

to 5 per second) occurred oftenest in the open, penetrating brain injuries — 29 and 17 per cent, respectively. Slow-wave focus Grade II was found in 18 per cent and Grade III in 3 per cent of cases with open nonpenetrating injuries. Only 3 per cent of patients with closed head injuries showed any slow activity. Generalized dysrhythmic records were seen in 20 per cent of open, nonpenetrating brain injuries and in 19 per cent of the closed head injuries. The spike-wave type of activity was present in 20 per cent of the penetrating brain wounds, 12 per cent of the open nonpenetrating injuries and in only 1 per cent of the closed head

traumas. After a lapse of three or four months, it was noted that the slow-wave focus frequently seen in open or penetrating brain injuries disappeared, and a spike-wave focus often became evident and undoubtedly indicated the development of cortical scars. Approximately 60 per cent of the patients showing spike-wave foci in the electroencephalograms developed convulsive seizures, and the presence of meningeal scars was confirmed at operation in several cases.

Clinical improvement and the lack of the so-called "post-traumatic syndrome" seemed to be more evident in the open or penetrating head injuries, although the electroencephalograms in these cases often remained grossly abnormal long after the patient had become better. This was in distinct contrast to the closed or minor head injuries, in which the electroencephalograms rapidly improved but the patient continued for many months to have headaches, dizzy spells, nervousness and so forth.

To determine the number of patients developing epilepsy after head injuries, a follow-up letter was given to each patient on discharge from the service. The patient was instructed to return these letters at the end of three months or immediately following any convulsive episode. This form letter requested the patient to describe any spells in detail, the date of the seizure and whether or not he was on medication at the time. Incomplete returns from these letters and from personal correspondence or subsequent observation of the patients indicate that to date about 24 per cent of patients with open, penetrating injuries of the brain in this series have developed post-traumatic epilepsy, in contrast to only about 5 per cent of those with closed or non-penetrating brain injuries. Since the electroencephalograms of about 60 per cent of patients with post-traumatic epilepsy demonstrated spike-wave or fast wave foci, it is quite suggestive that severe head injuries showing this type of electroencephalographic activity may sooner or later develop seizures and perhaps the early administration of anticonvulsive drugs may help to keep the patient free from seizures.

SUMMARY AND CONCLUSIONS

The results of 1470 electroencephalographic records in neuropsychiatric disorders among 950 soldiers are presented.

The head injuries made up the largest group tested (965 records) and included 141 electroencephalograms on open nonpenetrating injuries, 487 on brain wounds of the penetrating type and 337 on closed head injuries. The most frequent electroencephalographic abnormality in the open

nonpenetrating brain injury was generalized dysrhythmia and a slow-wave focus of 2 to 5 per second. A severe slow-wave focus of 0.5 to 5 per second was seen most frequently in penetrating brain wounds. A spike-wave focus was present in 12 per cent of nonpenetrating head injuries and 20 per cent of penetrating injuries. The tracings of about 60 per cent of patients developing post-traumatic seizures at one time or another showed spike-wave patterns.

Forty-seven per cent of patients with suspected epilepsy had abnormal records, the greatest majority being of the grand-mal type. No patients with post-traumatic epilepsy were included in this group.

Electroencephalograms on 24 different cases of migraine gave a definite abnormality in 33 per cent of subjects, whereas headaches of undetermined origin showed only 15 per cent.

Cases of cerebrovascular accident gave a fairly high percentage of abnormal activity (40 per cent). Brain tumors yielded 55 per cent abnormal activity, and of these abnormal records 37 per cent were definitely focal with the presence of the tumor confirmed by operation.

Patients with psychoneuroses showed only 6 per cent abnormal records. The frank psychoses, however, gave 16 per cent abnormal tracings, suggesting that the psychoses have some effect on brain waves — mainly a disturbance in the basic alpha rhythm.

Of the miscellaneous disorders tested, postmeningitic and postencephalitic syndromes showed the greatest number of abnormalities in the electroencephalograms.

The electroencephalogram is of definite value in localizing the greatest point of damage in brain injuries by the presence of a severe slow-wave focus. After three or four months this focus is frequently replaced by a spike-wave focus.

The electroencephalogram is also considered to be of definite aid in the diagnosis of various types of epilepsies and related disorders. It is useful in localizing brain tumors, provided the tumors are near the surface of the cortex and are not accompanied by increased intracranial pressure. Several cases of migraine showed abnormal records, suggesting that this malady is, at least electroencephalographically, related to the epileptic disorders. In all other neuropsychiatric disorders tested, the electroencephalograms were of doubtful or negative value.

MEDICAL PROGRESS

ENDOSCOPY (Concluded)*

EDWARD B. BENEDICT, M.D.†

BOSTON

GASTROSCOPY

Instruments

Six years ago Kenamore described a biopsy forceps for the flexible gastroscope. In a study of gastric lesions by means of biopsy specimens removed endoscopically, Kenamore, Scheff and Womack⁴⁶ presented 4 cases illustrating the value of the instrument as a positive method of differentiating benign and malignant gastric lesions. The instrument, which in trained hands is regarded as safe and as offering a method of more exact study of gastric diseases, is a flexible steel cable of fine caliber that can be attached externally to the gastroscope, whose diameter is thereby increased by only 3 mm. There is much to be gained by a suitable gastroscopic biopsy forceps, but I should much prefer to have such a forceps incorporated into the instrument, thus eliminating any external attachments that might interfere with smooth passage.

Hufford⁴⁷ has described a new light-weight flexible gastroscope known as the Eder flexible gastroscope, whose principal advantages are claimed to be reduced diameter of the flexible section by approximately 3 mm, greater flexibility, reduced weight and a superior optical system, with better magnification. Hufford considers this flexible gastroscope easier to handle and to manipulate, with less discomfort and tension on the part of the patient.

Technic

Robinson⁴⁸ believes that fluorescein aids in outlining and demonstrating a gastric ulcer and thus makes possible a more accurate estimate of diameter of the ulceration at the time of gastroscopy. Ten cubic centimeters of fluorescein is introduced into the stomach through an Ewald tube after the gastric contents have been drained. Gastroscopy is carried out in the usual manner.

Complications

Paul and Antes⁴⁹ reported a perforation of the esophagus by the flexible gastroscope resulting in retropharyngeal abscess formation. Prompt recognition and treatment effected a cure. The complication has become rare since the introduction of the flexible gastroscope.

Berk⁵⁰ observed a case of pneumoperitoneum following gastroscopy without evidence of perforation at laparotomy fourteen hours later. Gastroscopy was accomplished without difficulty, and mucosal details could be seen after inflation. The striking feature of the examination, however, was the fact that the stomach could not be kept inflated. After removal of the gastroscope, the patient complained of a sense of fullness and tightness, and physical examination showed signs of pneumoperitoneum. At operation there was no fluid collection and no evidence of inflammation or peritonitis on the serosal surface of any of the viscera. Thorough examination of the stomach and the abdominal portion of the esophagus failed to disclose any tear or perforation. The abdomen was closed tightly without drainage. Convalescence was uneventful.

Gastroscopic Studies

Howard⁵¹ asks the question, "What is the real value of gastroscopy?" According to him, gastroscopy enables one to see clearly a large part of the interior of the stomach, to visualize most gastric tumors and some gastric ulcers and to diagnose gastritis more properly. The gastroscope is a useful adjunct to the x-ray apparatus but does not supplant it. The diagnosis of chronic gastritis is the unchallenged field of gastroscopy, for the condition of the stomach's mucosa can be determined much better by direct inspection than by inferences from the study of its secretions or from the rugal pattern on the roentgenograms. Frequently, the height of the rugae is controlled by the tone of the muscularis mucosae, and elevated folds seen on the skiagrams can be ironed out by the inflation of the stomach with air. With the gastroscope reddening of the mucosa, edema, ulcerations resembling canker sores and a granular mucosa may be observed, sometimes, nodules are seen on the folds, or there may be atrophy of the gastric mucosa with striking thinning and a blue-gray color.

Dyspepsia and Gastroscopy in the Armed Forces

Before Pearl Harbor, Tavares⁵² examined by gastroscopy 100 consecutive military patients. He believes that as a diagnostic procedure gastroscopy deserves the place in military medicine, in peacetime or in war, that it merits in civil practice. The outstanding indication for gastroscopy was the group of conditions consisting of the dyspepsias.

*From the Massachusetts General Hospital.
†Instructor in surgery, Harvard Medical School, endoscopist, Massachusetts General Hospital.

present in 72 per cent of patients. A normal stomach was found in 20 per cent of cases examined. By far the largest group under the general classification of gastritis consisted of 25 patients with superficial gastritis.

Halsted et al.⁴² correlated gastroscopic and psychiatric studies of soldiers with chronic or non-ulcerative dyspepsia. Their study included 110 combat soldiers in a field hospital in the Fifth Army area in Italy during a seven-week period of static warfare. Clinical, roentgenographic, psychiatric and gastroscopic observations were made. The gastric mucosa was normal in 59 per cent of cases, and mild to moderate abnormalities consisting of redness, edema and exudation were observed in 41 per cent. There was no correlation between the appearance of the mucosa and the symptomatology, the symptoms being the same whether or not the mucosa was normal. Eighty-four and a half per cent of the total and 75 per cent of patients with gastroscopic abnormalities had a psychoneurosis, 15.5 per cent were psychiatrically normal. The clinical study is suggestive that the gastroscopic abnormalities noted — being those of superficial gastritis — represented functional circulatory changes resulting from nervous tension rather than the signs of organic disease.

Schwartz and Perlmutter⁴³ made a gastroscopic, roentgenologic and psychiatric study of chronic dyspepsia in the Mediterranean Theater. Gastroscopy was important as the only accurate method available for ruling out or confirming the diagnosis of chronic gastritis. Seventy per cent of subjects examined showed definite psychoneurosis. Chronic gastritis was the admitting diagnosis in 11 cases, but in only 4 was this confirmed by gastroscopic examination.

Chamberlin,⁴⁴ in a brief comment on gastroscopy in a report on military gastroenterology, states that "gastroscopy was a useful augmentation to the armamentarium of the gastroenterologist at war, but would have been more so had there been more gastroscopes and more gastroscopists."

Acute Gastroenteritis

Schwartz⁴⁵ examined by gastroscopy 20 patients who had recovered from a severe acute gastroenteritis as a result of food poisoning. Gastroscopy was performed three or four weeks after the onset of symptoms. He concluded that there was a lack of correlation between the gastroscopic findings and the symptoms in the majority of patients examined.

Atrophic Gastritis

Ortmayer, Balkin and Humphreys⁴⁷ report a case of chronic erosive granulomatous atrophic gastritis in which x-ray examination showed a constant narrowing in the prepyloric region with absent peristalsis and apparent shortening of the antral lesser curvature. Gastroscopy also gave the impression

of a narrowed antrum. A yellowish-white area extended from the lesser curvature of the antrum across the anterior margin of the angulus and 4 cm higher along the lesser curvature of the body of the stomach. This area was certainly an extensive erosion. Its proximal margins were reddened. The musculus sphincter antri looked infiltrated and stiff. In the higher stomach blood vessels were visible. The clinical diagnosis was carcinoma of the antrum and lesser curvature, with atrophic gastritis. At operation a rather soft lesion was palpated on the lesser curvature. The resected specimen showed a 4-by-5-cm., shallow, irregular ulceration that was barely perceptible. The pathological diagnosis was subacute to chronic granulomatous ulcerative gastritis, with no clue to its etiology. The authors believe that this interesting lesion has not previously been described.

Chronic Gastritis

In a study of chronic gastritis, Maimon and Palmer⁴⁸ state that the interpretation of the gastroscopic findings is not always easy, since variations in the appearance of the gastric mucosa noted with repeated examinations of the same stomach are extremely frequent. The frequent transition from one to the other suggests that the two may be variants of the same process. In a case reported no correlation between the gastroscopic findings and the clinical course of the patient could be noted. In another case seven gastroscopies for gastric ulcer were performed during a four-year period. The first revealed severe atrophic gastritis of the upper half of the stomach associated with areas of hemorrhage, confirmed by four succeeding examinations in the following years. Subtotal gastrectomy was carried out because the ulcer continued to recur. Histologic examination disclosed, in addition to a benign gastric ulcer, diffuse atrophic hemorrhagic gastritis and metaplasia to an intestinal type of lymph node. Gastroscopic examination of the remaining stomach three years later disclosed a normal mucosa. Even with severe changes, including metaplasia, atrophic mucosa may return to normal or at least form a normal-appearing surface. In general, however, the observations indicate that severe and widespread atrophy tends to continue unchanged. Furthermore, the return of the mucosa to a gastroscopically normal appearance does not prove the presence of a normal mucosa, for, as in pernicious anemia during a therapeutic remission, the apparently normal mucosa is unable to secrete acid gastric juice. There seems to be considerable evidence of an etiologic rather than an accidental relation between pernicious anemia and tumors of the stomach. The conclusions of Maimon and Palmer are as follows:

Chronic gastritis as diagnosed gastroscopically toward a persistent or recurrent course with predictable variations in type, severity and

the stomach. Repeated examinations of two patients with quite consistently normal findings suggest the tendency of the normal stomach to remain normal. On the other hand, phases of normality were not infrequently found in stomachs usually exhibiting a chronic gastritis of one kind or another. Repeated examinations in individual patients over periods varying from two to eleven years suggest that superficial and hypertrophic gastritis may be variations of the same process rather than separate and distinct entities. The prognostic implications of both the moderate and severe grades of superficial and hypertrophic gastritis are not significantly different, both tending to prolonged chronicity. Atrophic changes without an admixture of the superficial or hypertrophic types were observed to be constant for periods up to five years, on the other hand, in some cases atrophic gastritis did seem to appear as a sequela of hypertrophic and superficial gastritis. Atrophic gastritis, when severe, tends to persist, but return to normal has been observed. Atrophic changes are more frequent in the upper third of the stomach whereas superficial and hypertrophic changes occur more often in the middle portion. Gastritis of various types has been observed gastroscopically in many examinations in 14 patients over periods up to eleven years in duration without detectable serious consequence. In these 14 patients it has not been possible to correlate the appearance of the gastric mucosa with symptoms of any kind. While mucosal changes were observed in 6 patients subjected to x-ray therapy the type of change was not constant or consistent and could not be correlated with the appearance of the mucosa prior to roentgen irradiation or with therapy itself. Two patients with both superficial and hypertrophic gastritis prior to supradiaphragmatic bilateral vagotomy were found to have only superficial changes after the operation. Regardless of attractive theoretical considerations the clinical significance of chronic gastritis remains unproved.

Edematous Gastritis

Loeper⁵⁹ believes that the condition that he calls "edematous gastritis" is caused by the ingestion of certain foods, particularly mollusks, crustacea, fish and sausage. It often alternates with urticaria, of which it seems to be an internal manifestation. Gastroscopy assists in the diagnosis. An edematous swelling of the mucosa, with a pale central zone and a darker periphery, may be present. The duration of the edematous gastritis may be from two to eight days. Treatment consists of a strict diet and administration of bismuth and charcoal. Desensitization may be effected by the administration of peptone and pepsin prior to meals.

Postoperative Gastritis

According to Christiansen,⁶⁰ postoperative gastritis is characterized by polymorphism. There are superficial, hypertrophic, erosive, atrophic or ulcerous elements. The condition develops independently of the presence of free hydrochloric acid or of the ability of the stoma to attain rhythmic contraction. If objective improvement occurs, it affects only the erosive and ulcerative elements, the atrophic and hypertrophic changes appear irreversible. Effective therapy is not known. The most helpful treatment is perhaps a combination of ulcer diet and gastric lavage, but subjective improvement is not always accompanied by objective improvement, and in spite of amelioration the gastritis may progress. Postoperative gastritis must be considered one of the gravest disorders of the stomach.

Gastric Ulcers

Ricketts and Pollard⁶¹ analyzed 1297 patients, who were studied both by x-ray examination and by gastroscopy. In 172 cases in which both examinations were negative no satisfactory clinical diagnosis was made in 60, in 112 cases the clinical diagnoses comprised a wide variety of extragastric disorders and diseases. In the 355 cases with conflicting gastroscopic and roentgenologic findings gastroscopy failed to reveal lesions visible on x-ray study in 46 cases, including 22 of benign ulcer, 21 of carcinoma (11 proved at operation or necropsy), 2 of benign polyposis and 1 of gastric diverticulum. Conversely, positive gastroscopic and negative roentgenologic findings were obtained in 309 cases, including 269 of chronic gastritis, 26 of benign ulcer, 10 of carcinoma (the diagnosis being proved at operation or autopsy in 5 cases) and 4 of benign polyp, 1 with malignant degeneration. Three cases with a gastroscopic and roentgenologic diagnosis of carcinoma proved on histologic examination to be tumor-like gastritis. In the complete clinical study of gastric disease, gastroscopy and x-ray study are invaluable, although not infallible, procedures.

Pollard, Bachrach and Block⁶² believe that with further advances in diagnostic technic, particularly regarding gastroscopic visualization, it may become possible to determine more accurately from the size and appearance of an ulcer whether it is likely to heal under adequate medical management, and how soon healing can be expected.

Brick⁶³ has written a preliminary report on irradiation effects on the stomach with a 1,000,000-volt machine. A case of ulceration of the stomach with perforation and hemorrhage as a result of irradiation successfully treated surgically has been reported, as well as a case of gastroscopic confirmation of an ulcer noted by x-ray examination. The importance of these observations lies in obtaining accurate knowledge about the tolerance of various human tissues in this age of supravoltage and atomic energy.

Carcinoma

Rickles⁶⁴ reports a case in which five primary cancerous lesions of the stomach were present and were treated by transthoracic gastrectomy. Pathological study of the specimen showed an ulcerating carcinoma of the cardiac end of the stomach and four papillary adenomas of the gastric mucosa apparently arising from adenomatous polyp. These tumors were separated by normal mucosa and submucosa.

Maimon and Palmer,⁶⁵ in a review of the incidence and diagnostic procedures in gastric carcinoma, state that the value of prolonged and repeated gastroscopic examinations cannot be too strongly stressed, since parts of the stomach not clearly visualized at one examination were frequently seen at the time of another examination.

several days or weeks later. The change in the appearance of a lesion was often so marked in a few days that the examiner was able to make a correct diagnosis even though this had not been possible at the time of the initial examination. Differences in peristaltic action, spasm and the superficial appearances of a lesion may well account for the changing picture. Although gastroscopy is a valuable adjunct in the diagnosis of gastric carcinoma the criteria for determining the resectability of a lesion by this method need further study. The correct diagnosis was made in 84.6 per cent of 163 patients so examined. In 15.4 per cent the examination was inconclusive owing to the technical difficulties preventing satisfactory passage of the instrument or failure to visualize the lesion, or the diagnosis was incorrect because of inability to differentiate neoplasm from ulcer, hypertrophic gastritis, lymphoma and sarcoma.

Schindler⁶⁵ has discussed the relative surgical curability of certain gross types of gastric carcinoma. He believes that microscopical grading is not too reliable and that perhaps a better method would be to base the prognosis and the therapeutic procedure on gross types of carcinoma. The Borrmann classification has been used in which Type I is the sharply limited polypoid tumor, accounting for 2.9 per cent of all gastric carcinomas. Type II, which is also a sharply limited tumor, consisting of an ulcer surrounded by an elevated wall sharply demarcated all around, occurs in 17.6 per cent. Type III, which occurs in 16.3 per cent, is also sharply limited, consisting of an ulcer surrounded by an elevated wall, but the wall does not surround the whole circumference of the ulcer, the ulcer blending diffusely at some point with the neighboring mucosa. Type IV comprises the diffusely infiltrative tumors (63.2 per cent). There is some evidence that Types I and II are relatively more curable than Types III and IV. By a combination of x-ray study and gastroscopy the gross type of a gastric carcinoma can usually be identified reliably before operation.

Moerach and Kirklín⁶⁷ compared gastroscopy and roentgenology in 100 selected cases of proved carcinoma of the stomach. The diagnosis by gastroscopy was correct in 70 cases, indeterminate in 10 and incorrect in 20, and that by x-ray examination was correct in 52 cases, indeterminate in 6 and incorrect in 42. The source of greatest error in gastroscopic diagnosis of carcinoma of the stomach was in the differentiation of this lesion and severe hypertrophic gastritis. It is pointed out that repeated roentgenologic examination of the stomach is sometimes required before a definite opinion regarding the presence or absence of a gastric lesion can be expressed and, if one is present, its character determined. In contrast, it is too frequently assumed that a definite opinion should be expressed as a result of a single gastroscopic examination. That repeated gastroscopic examinations are often as essen-

tial as repeated roentgenographic examination in arrival at a correct diagnosis is well illustrated by the data presented. The authors conclude that roentgenology is preferable to gastroscopy as a routine procedure in the diagnosis of carcinoma of the stomach, because of its ease of performance, rapidity, greater safety and the fact that there are fewer contraindications to its use than to that of other methods. Gastroscopy is of extreme value as an adjunct to roentgenology and clinical diagnosis in the study and diagnosis of carcinoma of the stomach. This is especially true in cases in which the roentgenologic findings are indefinite and in those in which the roentgenologic and clinical observations are at variance. The close collaboration of the gastroenterologist, roentgenologist and gastroscopist is of great importance in improving the chances of earlier diagnosis of carcinoma of the stomach.

Stout⁶⁸ studied 150 resected stomachs and found atrophic changes in 50 per cent of cases with duodenal ulcer, 60 per cent with gastric ulcer and 94 per cent with gastric carcinoma. It is apparent that atrophic changes and cyst formation accompany carcinoma of the stomach, but to detect a causal relation, one must find cancer epithelium and gradations between altered cells. Such a relation has not been proved.

Leiomyosarcoma

Schindler and his associates⁶⁹ discussed the roentgenologic and gastroscopic diagnosis of leiomyosarcoma of the stomach and its possible relation to pernicious anemia. In the 4 cases considered the diagnosis of a gastric tumor was missed at one x-ray examination in 1 case and at two in another. In these cases the presence of a gastric tumor was found at gastroscopy. In both cases the tumor could be demonstrated at a repeat x-ray examination when the proper technic was used. These cases prove the fact that the method of filling the stomach completely with barium suspension and then taking films is unsatisfactory. The barium must be replaced routinely by the relief method. The diagnosis of benign submucosal tumor at x-ray examination can be hazarded if a sharply defined round filling defect with a central niche is noted. The authors state that in none of 4 cases was the correct diagnosis made at gastroscopy but that in 2 features were described in the gastroscopic protocol that had a certain relation to submucosal tumors and this relation had been stated. The important gastroscopic finding is that of a soft, protruding mass with hemispherical protrusion sloping gently toward the gastric wall. The authors conclude that in 3 cases the x-ray diagnosis would not have been impossible and that in 3 cases the correct gastroscopic diagnosis should have been made. In 1 case there was the possibility of pernicious anemia leading to the formation of leiomyosarcoma.

Isolated Hodgkin's Disease

Browne and McHardy⁷⁰ reported 2 cases of isolated Hodgkin's disease of the stomach in the first of which gastroscopy revealed in the proximal two thirds of the stomach a widespread polypoid hyperplasia with nodulations and ulceration, covered in part by a grayish exudate, seemingly held rigid, but remarkably distensible and with an uninvolved pyloric segment. In the second case gastroscopy was not done. The authors believe that a clinical diagnosis cannot practicably be made with present knowledge of the disease, but that in its simulation to neoplastic disease it often manifests itself sufficiently early and significantly to indicate resection.

Hemorrhage from Gastritis

Jones⁷¹ emphasizes the fact that gastritis alone is occasionally the source of an exsanguinating loss of blood. In the absence of definite roentgenologic findings, or when supplemental evidence regarding the nature of the bleeding lesion is desirable, endoscopic examination should be performed as soon after major bleeding has ceased as it can safely be done. Gastroscopy, in experienced hands, is the only way to demonstrate an active gastritis that is responsible for upper-segment hemorrhage.

Schatzki⁷² also believes that gastritis may cause marked hemorrhage, particularly if many erosions are present. The roentgenologic diagnosis of gastritis is difficult and is possible in only a small number of cases. The erosive form, in which bleeding is most frequent, is rarely demonstrable, but if it is, the characteristic appearance is one of multiple shallow craters surrounded by a halo of edema. In acute alcoholic gastritis, which often causes hemorrhage, evidence of marked hypersecretion, with some swelling of the folds, is seen. At times this swelling produces a tumor-like appearance, but it usually disappears within a few days. On the other hand, in gastritis, the stomach may appear completely normal roentgenologically, and only by gastroscopy may the diagnosis be made.

Hereditary Hemorrhagic Telangiectasis

Kushlan⁷³ has reported a typical case of hereditary hemorrhagic telangiectasis with chronic gastrointestinal bleeding of fifteen years' duration. Gastroscopy offers an invaluable aid in determining the presence of the characteristic lesions in the stomach, since x-ray examination of the gastrointestinal tract appears to be of no value in these cases. Rutin therapy may represent the long sought for specific remedy for hereditary hemorrhagic telangiectasis.

Salicylism

Caravati⁷⁴ performed gastroscopy on 20 patients during salicylism. The stomach was satisfactorily visualized in each case but no abnormality of consequence was observed except in a case that showed

moderate increase of highlights with erosions of the gastric mucosa visualized at Depth two. This was thought to represent probable localized minimal superficial gastritis.

Gastroscopy in Acute and Chronic Hepatitis

Bank and Dixon⁷⁵ made gastroscopic observations in 43 cases of acute and chronic hepatitis. In no case did gastric symptoms exist prior to the onset of hepatitis. X-ray examinations of the stomach, duodenum and gall bladder were negative in all. Gastroscopy did not reveal significant evidence of gastritis. The minimal findings observed in some patients were not considered contributory to the patient's gastrointestinal symptoms.

Gastric Varices

Although esophageal disease is usually a contraindication to gastroscopy, Moersch⁷⁶ believes that gastroscopy should be considered in cases of esophageal varices in which injection of the varices with a sclerosing solution is contemplated. Inspection of the stomach is advisable to determine whether or not varices are present in the stomach. In the experience of Moersch, injection of esophageal varices will be disappointing if varices are also present in the stomach. Although gastric varices can be identified in a high percentage of cases on roentgenologic examination, gastroscopy has been found more accurate in this respect than roentgenologic methods. So far, Moersch has encountered no difficulty as a result of gastroscopy in the presence of esophageal varices, but it is not advisable to carry it out during an active phase of bleeding.

PERITONEOSCOPY

Needle Biopsy of Liver

Peritoneoscopy is so frequently performed to obtain a biopsy of the liver that it seems only fair to mention the alternative method of needle biopsy. This can apparently be done safely in most cases of diffuse liver disease but is done blindly and will not be likely to pick up isolated areas of metastatic carcinoma.

Davis, Scott and Lund,⁷⁷ have performed needle biopsy of the liver on 68 patients since 1939. They have found the procedure most useful in the diagnosis of carcinoma of the liver and in establishing the nature of a diffuse parenchymal disease, including cirrhosis. There were no fatal cases.

Van Beek and Haex⁷⁸ have obtained valuable information from aspiration biopsy of the liver in a case of infectious mononucleosis and in 4 cases of sarcoidosis.

Cirrhosis of the Liver

The treatment of cirrhosis of the liver is beyond the scope of this report, but it is of interest that the result of treatment at varying intervals of time can

be advantageously studied by needle biopsy of the liver or by biopsy obtained at the time of peritoneoscopy.

Recent advances in the therapy of cirrhosis have been discussed by Morrison¹⁹ in a series of 62 patients studied from 1938 to 1945. These patients were divided into three groups according to the method of treatment most advisable at the time. The best results were obtained in the third group of 20 patients, who were treated intensively with a combined therapy consisting of a maximum protein, high-carbohydrate, low-fat diet, daily injections of 5 cc of a whole-liver extract, highly potent injections of components of the vitamin B complex, daily components of the vitamin B complex orally and multiple vitamin capsules orally, together with 2 gm each of methionine and choline daily. The intensive combined method of therapy resulted in a remission of all signs and symptoms in 64 per cent of cases in the group without ascites, as compared with remissions in only 10 per cent of cases in the control group, in the group with ascites remission occurred in 34 per cent of cases, as compared with none in the corresponding control group.

Lovry, Ashburn and Sebrell⁶⁰ maintained rats on a cirrhosis-producing diet for sixty-three to eighty-four days, and the status of the liver of each rat was determined at that time by biopsy. The rats were then treated by the daily administration of large amounts of choline chloride or by the use of a diet containing large amounts of casein. The gross and microscopical appearance of the liver after treatment was compared with the biopsy findings. During the period of treatment a striking improvement in the gross and microscopical appearance of the liver occurred. Although therapy did not have a recognizable effect on the fibrous tissue present, it apparently prevented further progression of the cirrhotic process and produced improvement in the microscopical appearance of the parenchyma.

Value of Peritoneoscopy

Miqueo Narancio et al⁸¹ have used the peritoneoscope chiefly in the attempted determination of inoperability, in borderline cases when clinical evidence of such inoperability does not exist. They have evaluated the procedure from the following three standpoints: the possibility of avoidance of an unnecessary celiotomy, the rate of operative mortality and morbidity of exploratory celiotomy vs peritoneoscopy, and the economic factor. In their series peritoneoscopy disclosed the disease to be so extensive that exploratory celiotomy was avoided in 39 cases, or 48.8 per cent. The average duration of hospitalization of these patients was forty-eight hours. The single death that occurred in the group of 80 patients was the result of intraperitoneal hemorrhage in a patient with cirrhosis of the liver and a low prothrombin level. No obvious source of bleeding could be found on post-mortem examination.

This record may be contrasted with that for exploratory celiotomy for cancer which is generally in the neighborhood of 8 per cent. The brief period of hospitalization is of economic significance to the patients. At present the total minimum cost to a patient occupying an inexpensive private room for two weeks is \$195 with anesthesia and operating-room charges, compared to a cost of \$58 for peritoneoscopy.

CASE 33301

PRESENTATION OF CASE

A seventy-three-year-old woman entered the hospital because of swelling of the right leg

She had been well until five weeks before entry, when, just after going to bed, she suddenly had a chilly sensation and began to feel feverish. At the same time she developed a severe productive cough, yielding about a cupful of clear, liquid sputum a day. Her strength gradually ebbed until she could no longer leave her bed. She subsisted on milk and soups. Two days before entry the district nurse, who stopped daily to bathe the patient, noticed that the right leg was swollen. The patient herself had observed only that the leg was "heavy." It had not been painful, cold or numb.

Twenty-nine years before entry the patient had had epidemic influenza complicated by slight swelling of the right leg and pain deep in the calf. She was told that she had phlebitis and myocarditis. For about twenty years she had had mild "bronchitis." Four years before entry she began to have difficulty in climbing the two flights of stairs to her apartment because of exhaustion and some dyspnea. She slept on two pillows. She denied ever having experienced chest pain or palpitation. The weight had been over 250 pounds for many years. She did not believe that she had lost much weight during the present illness.

Physical examination revealed an extremely obese woman lying flat in bed without distress. The skin was thick and dry. The eyebrows were thick, but there was no axillary hair and the pubic hair was sparse. There were a few rales at the left base. The heart sounds were faint and irregular, with what were apparently frequent extrasystoles. The abdomen was normal, except for the extreme obesity. Brawny swelling of the right leg up to the groin was noted, and there was pitting edema over the foot, which was cyanotic and slightly cooler than the left. Dorsalis pedis and posterior tibial pulses were palpable and equal on

100°F, the pulse 70, and blood pressure was 140

Examination of the blood showed a hemoglobin of 12.2 gm and a white-cell count of 18,350, with 86 per cent neutrophils. The urine was normal, except for a + test for albumin. A stool was brown and formed and gave a negative guaiac test.

An x-ray film of the chest disclosed a wedge-shaped area of increased density, extending upward and forward from the left lung root in the upper lobe to the anterior chest wall. The cardiothoracic ratio was 15/27. An electrocardiogram showed auricular fibrillation and a ventricular rate of 70. The voltage and axis were normal. There were sagging ST segments in Leads 2 and 3, slightly low and upright T waves in Leads 1, 2 and 3, a small R wave and a flat T wave in Lead CF₂, a slightly sagging ST segment in Lead CF₄ and upright T waves in Leads CF₄ and CF₆.

The patient was placed on bed rest and a low-salt, reducing diet. A second x-ray film of the chest on the tenth hospital day showed no change. On the eleventh hospital day the patient was cyanotic and moaning in short gasps. The blood pressure was not obtainable. After fifteen minutes the heart beat and respirations ceased.

DIFFERENTIAL DIAGNOSIS

DR RICHARD J CLARK: May we see the x-ray films? This, I assume, is the band of density described.

DR TOUFIC H KALIL: Yes, it was described as going diagonally upward.

DR CLARK: I judge that the heart was displaced to the right—at least there seems to be considerable prominence on the right side. This band of density in the lateral view does not show up particularly well in the anteroposterior view.

DR KALIL: For that reason I think that it is probably not a band of atelectasis. There is no reason to suspect that atelectasis was present in the upper lobes.

In this lateral view the anterior margin of the trachea is displaced posteriorly.

DR CLARK: What about the hilar shadow?

DR KALIL: That is an unusual shadow. The pulmonary trunk is markedly enlarged, and the comma-shaped shadows on each side are markedly enlarged. Right and left pulmonary arteries. The left main bronchus is displaced downward. Usually, that means a collapsed lower lobe. In this case it is pressure from the large left pulmonary artery above. There is no increase in markings on the left, but there is some in the right lower lobe, representing atelectasis.

DR CLARK: Would you care to say whether that shadow, from the x-ray point of view, is consistent with a pneumonic process?

DR KALIL: No, it is not.

DR CLARK: I think that this is an example of a case in which the impression of the x-ray picture from the description in the record is quite different.

from that produced by the actual films. I am taken aback by the appearance of the x-ray films.

This case involves problems regarding the leg, the lungs, the heart and finally the mode of exitus. Although there may be interrelations, I shall take the points up separately.

Twenty-nine years prior to entry the patient had an episode consistent with acute phlebitis in the right leg. We are told nothing of any interim difficulty. Two days before admission, edema of the right leg was again noted, but apparently with little other symptomatology than a "heavy" sensation. This appeared after about five weeks of bed invalidism. Cases of unilateral leg edema first bring to mind a local circulatory disturbance. The leg was slightly cyanotic and cool, but showed palpable arterial pulses. Nothing is said regarding tenderness. The possibility of a pelvic mass that produced unilateral venous stasis must be considered, but we are told nothing regarding rectal or pelvic examination, and there is no way in which I can arrive at any such diagnosis. I am left with the conclusion that a recurrent phlebitis of the leg must have developed.

Next comes the problem of the lung lesion. Five weeks before admission there was a sudden onset of chilly sensations and feverishness associated with a severe productive cough and the raising of clear, liquid sputum. The presence or absence of blood is not mentioned. Apparently, there was no chest pain. This process was accompanied by progressive loss of strength. On entry the lungs showed only a few rales at the left base, but on x-ray examination there was the wedge-shaped lesion that we have seen. We may reasonably assume that the x-ray findings were associated with the sudden onset of the illness five weeks previously. The possibilities to consider are, first, cancer, second, tuberculosis, third, pulmonary infarction and, finally, an acute pneumonic process. The polymorphonuclear leukocytosis on entry was most probably associated with the leg lesion and cannot influence strongly the diagnosis of the lung lesion. In spite of the history of bronchitis for twenty years, I consider the onset too abrupt to have been associated with primary cancer of the lung, nor does the x-ray description especially suggest this. For practically the same reason, I shall dismiss tuberculosis. A pneumonic infection of the virus type could give the entire lung picture and not infrequently drags out over a period of several weeks, with continuation of x-ray changes. With such an infection there may well be associated atelectasis. The acute process may also have resulted from pulmonary infarction. The onset is by no means typical of the classic description of pulmonary embolism, but we have learned increasingly in recent years that vague symptoms of pneumonia, especially in patients with cardiovascular disease, often represent infarction of the lung. It is possible that this patient had one of

the insidious, slowly progressive types of phlebitis at the onset, which manifested itself only in producing an embolus but which subsequently progressed to the point of venous obstruction. On the other hand, the location of the lesion in the left upper lobe is definitely against pulmonary infarction, and the progressive weakness fits better with a low-grade pneumonic infection. Also, it would be most unusual for an infarct of the lung to be so definitely wedge shaped and to show no change five and six weeks after onset. Pulmonary infarction does not usually induce the coughing up of a cupful of clear sputum daily. Although this consideration of pulmonary infarction intrigues me, I shall pass it by in favor of a pneumonic process, probably associated with some atelectasis.

Now we come to the question of the heart. For four years the patient had had exhaustion and dyspnea and had required two pillows to sleep comfortably. She was said to have had myocarditis, which means little, twenty-nine years previously. The heart sounds were distant and irregular, but no murmurs were described. On x-ray study the heart was enlarged, the borders extending 2 cm. beyond the average cardiothoracic ratio. Its shape was somewhat unusual, suggesting prominence in the region of the pulmonary artery and displacement toward the right. The electrocardiogram was abnormal but of a nonspecific pattern. The patient was fibrillating at a rate of 70. We are not told whether she was digitalized or not. The changes in the T waves and ST segments could have resulted from digitalis, or they could have represented some degree of coronary disease. Absence of left-axis deviation and of an upright T wave in Lead CF, are against hypertensive strain. Absence of right-axis deviation is against cor pulmonale. The one blood pressure reading given was essentially normal, but this was after a debilitating illness and the patient may have had an elevated pressure earlier. The x-ray appearance is not that of a hypertensive heart. With a pulse of 70 and flat, quiet breathing, I cannot believe that any important degree of congestive failure was entering into the picture, although we are told that she was placed on a low-salt diet. The presence of a thick, dry skin is noted, and yet the eyebrows were full. Sparse pubic and axillary hair need not be too significant in a woman seventy-three years of age. Again, a heart rate of 70, with a temperature of 100°F, especially if she were not digitalized, is extremely significant. I cannot but wonder if the patient had myxedema. In a study of patients with myxedema at this hospital a few years ago,¹ fairly marked cardiac enlargement was usually found, often simulating the water-bottle variety, and all types of T-wave variations occurred, often, but not always, with low voltage and with either a normal axis or left-axis deviation. In none of the cases studied here or reviewed in the literature was

auricular fibrillation found, even in those with hypertension, which was frequent. If this patient had myxedema, I should consider that she had some other form of heart disease. With a history of myocarditis of twenty-nine years' duration, together with the presence of auricular fibrillation and the absence of left-axis deviation and chest pain, the possibility of an undetected mitral stenosis cannot be overlooked, regardless of a negative past history.

Finally, we come to the immediate cause of death. There was a sudden exitus preceded by moaning and short, gasping breathing. Was this acute myocardial infarction with ventricular fibrillation or acute pulmonary edema, or was it a massive pulmonary embolus? The description is not that of acute pulmonary edema. Apparently, the heart beat was heard to the end. I should expect death from acute coronary thrombosis to be either more rapid or more prolonged, with evidence of pulmonary edema. The cyanosis and moaning, as well as the short gasps, in a woman who was already assumed to have had phlebitis, sound more like a massive pulmonary embolus to me, and on that I shall rest.

DR TRACY B MALLORY: Has anyone another suggestion?

DR ALFRED KRANES: About fifteen years ago Drs. Mallory and Means² reported the case of a patient with phlebitis and thrombosis of the pulmonary artery. The x-ray picture in the case under discussion looks like the one in that case, although the clinical picture is different.

DR MALLORY: Your memory is better than mine, Dr. Kranes.

DR HELEN S PITTMAN: This woman was the fattest I have ever seen. The reason no pelvic examination was done is that she was a human mountain and could not move herself. It was impossible to get her into position. She did not notice that the leg was swollen because she did not see the leg. I discussed the case with Dr. Linton and thought that the picture was consistent with infarction and that the pulmonary emboli had occurred weeks or months before the local evidence of thrombophlebitis. We sent out an emergency call for the Peripheral Circulatory Service, which was answered by Dr. Faxon.

DR HENRY H FAXON: To me, this was an interesting problem because, as Dr. Pittman has said, the patient was not exactly an ideal candidate for surgery. Unless one had seen the torso, one could not possibly imagine what the situation was. Another point of real significance is that, having seen her, one would agree that there was no question that she had had a deep phlebitis in the past, and without much doubt she had a recurrence of the deep phlebitis in the present. The right thigh was markedly larger than the left. It has been our belief—also expressed by Ochsner³ and others—that, if the thigh is swollen, the process of the deep

thrombophlebitis is marked enough and high enough and so adherent to the vessel that one is no longer faced with an indication for a femoral ligation. When we started to carry out this procedure in a few patients with swollen thighs, we exposed the femoral veins only to find that the clot was extremely adherent, and nothing was gained by the operation, the process had gone above that. In this case the question was therefore not whether I should do a femoral ligation, which I knew would be futile, but whether I should consider going high enough to do a ligation of the vena cava. That was not justified in any sense, being such a major procedure. As I have said, it is generally believed that if the thigh is swollen the patient is free of the danger of having a clot break loose. I made a note in the record dogmatically that at times large pulmonary emboli occur in patients with a swollen thigh either from another lesion above the point of attachment or from the unaffected leg. I did not consider myself justified in ligating the vein in this patient with deep phlebitis. The possibility of dicoumarol and heparin held only faint promise. The question always arises whether one should start therapy and keep anticoagulants going a long time until the patient can be mobilized again. It would have been a long time before this patient could have been active, so that I advised taking no surgical steps and only faintly encouraged the use of dicoumarol.

DR CLARK: Was she on digitalis?

A PHYSICIAN: She was not.

DR CLARK: Did you think that she had myxedema?

DR PITTMAN: No, we did not.

CLINICAL DIAGNOSES

Thrombophlebitis, right leg
Pulmonary embolus

DR CLARK'S DIAGNOSIS

Massive pulmonary embolus

ANATOMICAL DIAGNOSES

Pulmonary emboli, multiple, old and fresh
Infarcts of lung
Chronic thyroiditis, slight
Thrombophlebitis of right leg

PATHOLOGICAL DISCUSSION

DR MALLORY: Autopsy was limited to a thoracic incision so that we cannot answer all the questions that we might like to. The major finding was in the pulmonary artery, which contained two distinct recognizable emboli: an old one, which was grayish-white and adherent, and a fresh one, which was coiled in the main pulmonary artery and its primary branches. The latter was unquestionably the immediate cause of death. There were two infarcts

in the right lower lobe, one of which was so old that its center had lost its blood pigment and had become almost white. The second, a small one near the base of the right lower lobe, was more recent.

The heart was slightly hypertrophied, weighing 410 gm. We could find nothing particularly wrong with it. The coronary arteries were in excellent condition, showing little arteriosclerosis. We were able to examine the thyroid gland, which was normal in weight and showed slight focal inflammation and a little adipose tissue inside the thyroid capsule, suggesting a mild degree of atrophy but not enough to produce a significant degree of myxedema. There were no clots in the venae cavae or in the iliac veins. When the legs were elevated and squeezed we could force out no blood from the right side, whereas there was a free flow from the left, so that there was no evidence of disease on the contralateral side.

DR. CLARK: Can you explain the apparent shift of the heart to the right?

DR. MALLORY: No, we found nothing to explain it. We were not impressed by the degree of atelectasis in the right lower lobe.

CASE 33302

PRESENTATION OF CASE

A fifty-year-old single Irish truck driver was admitted to the hospital for abdominal pain.

For five days the patient had had continuous pain, starting in the epigastrium and gradually spreading to involve the entire abdomen. The appetite had fallen off, but the bowels continued to move in their usual fashion, with the customary daily laxative tablet. He had no bleeding by rectum and no nausea and vomiting until the day of admission, when he vomited recently ingested food but no blood.

Seven months before admission the patient had been admitted to another hospital for pneumonia, with coughing, dyspnea, chills and fever. At that time physical examination revealed a slight elevation in blood pressure and an enlarged heart. He was started on digitalis, which was continued thereafter. Two weeks later he resumed work but developed increasing dyspnea and after three months was again hospitalized. At that time the ankles were not swollen, and he could usually lie flat in bed. On discharge about two weeks later he was improved but was able to work only a couple of days,

he subsequently became increasingly dyspneic and orthopneic, and the ankles began to swell.

He had been admitted to this hospital two months previously because of obvious congestive failure, with a blood pressure of 160 systolic, 98 diastolic. The thyroid gland was palpable but not enlarged. The heart was enlarged, the border extending to the anterior axillary line, and the pulmonic second sound was louder than the aortic. There were no murmurs, but a protodiastolic gallop was described by one observer. Moist rales were heard at both lung bases, and the liver edge was palpated three fingerbreadths below the costal margin but was not tender. The neck veins were only slightly distended. There was moderate ankle and sacral edema. The urine gave ++ and +++ tests for albumin. An electrocardiogram revealed sinus rhythm, a rate of 100, a PR interval of 0.18 second, a QRS interval of 0.12 second, a low voltage and a tendency to left-axis deviation, with a flat T wave in Lead 1, low T waves in Leads 2 and 3, absent R waves in Lead CF, slight elevation of the ST segments in Leads CF and CF₄, an extremely small R wave in Lead CF₄, a small notched R wave in Lead CF, and upright T waves in Leads CF₄, CF, and CT. X-ray films of the chest showed prominent pulmonary vascular markings and a much enlarged left ventricle. Another film a week after admission revealed only slight clearing of the bases and a patch of increased density in the right lower lobe, which was more prominent than that on the previous examination. The patient complained of some nausea and continued to be short of breath. He was discharged about three weeks after admission on bed rest, a low-sodium diet, diuretics and digitalis.

On physical examination the blood pressure was not obtainable, and the heart sounds were regular but extremely faint. There were rales at both lung bases but no evidence of consolidation. The abdomen was distended, spastic and diffusely tender, with almost no peristaltic sounds. Rectal examination revealed a tender pouch of Douglas but no distinct masses. Dark-red blood was noted on the examining finger. The heart did not appear enlarged to percussion. There was no ankle edema and only slight edema over the sacrum.

The temperature was 100.4°F, the pulse 90, and the respirations 48.

Examination of the blood revealed a hemoglobin of 14.5 gm, a white-cell count of 13,300 and a hematocrit of 43 per cent. The total serum protein was 6.7 gm per 100 cc. A plain film of the abdomen disclosed considerable distention of the small intestine and what appeared to be stomach, with no evidence of distention or retained fecal material in the colon.

Shortly after arrival the patient vomited reddish-black material, which gave a ++++ guaiac test,

WHAT ARE HOSPITAL SERVICES?

THE new contracts of the Blue Cross, which went into effect on June 1, have again raised the question concerning the definition of hospital services. These contracts call for a per-diem allowance that is identical in any one hospital but varies from hospital to hospital according to the services ordinarily furnished and to the actual charges for such services in 1946 adjusted to current rates. "Services ordinarily furnished" are considered to include x-ray diagnosis and treatment, anesthesia and laboratory work when such services are rendered by employees of the hospital. To this interpretation, however, the radiologists, anesthesiologists and pathologists who are connected with the hospitals on either a

full-time, part-time or percentage basis have taken violent exception. Indeed, various organizations of these three groups of specialists presented resolutions at the annual meeting of the Council of the Massachusetts Medical Society that opposed any arrangement by a hospital with the Blue Cross that permitted the latter to guide or determine professional services that criticized the per-diem allowance because it fails to distinguish between hospital and professional services and that recommended that all charges for professional services by physicians should be excluded from hospital-service contracts. These resolutions were adopted by the Council, with the recommendation that a committee be appointed to investigate the matter.

Are x-ray diagnosis and treatment, anesthesia and laboratory work true hospital services? Certainly the maintenance of the respective departments, including the cost of equipment, supplies and nursing and technical personnel, is a hospital expense and hence should be included as hospital service. And the same reasoning seems to apply to those physicians rendering professional services who are paid by the hospital. Thus, the tendency "to guide or determine professional services" and the failure "to distinguish between hospital and professional services" now rests — and has for many years — with the hospitals rather than with the Blue Cross. In fact, the per-diem method of payment to hospitals, with one exception, calls for no change in the financial arrangements between the hospitals and their medically trained employees; it is essentially a change in accounting methods whereby a great deal of detailed bookkeeping on the part of the Blue Cross, as well as by the hospitals, will be eliminated.

The "fly in the ointment" appears to be the statement by the Blue Cross that the new contracts cover all ancillary charges regardless of the status of the patient. Just why this provision was passed by the governing board of the Blue Cross and accepted by the hospitals is difficult to understand. Obviously, the Blue Cross has less authority — in fact, none — to determine professional charges to a private patient than it has to decide what such a patient shall pay for his room and board. But the allowance for the latter is limited to a certain

figure, the patient being billed for the balance. The same scheme is employed for subscribers to the Blue Shield whose earnings are sufficient to remove them from the low-income group. In other words, it appears that the private patient should be allowed a credit for such services but that he should be billed directly for all charges above a predetermined maximum. That semi-private and ward patients are entitled to unlimited services may seem unfair, but it is likely that the charges for these services, taking into consideration the financial status of the patient, would not often exceed the credit permitted to the private patient.

Although this one point directly concerns the Blue Cross, all other matters of the controversy appear to pertain to the hospitals and their medically trained employees. Possibly it is improper for hospitals to charge for services of this type, if so, drastic changes in organization must be made. In any event, the report to the Council of the committee appointed to consider the matter will be awaited with interest.

THE TREND IN HEART DISEASE

It has been estimated that approximately 4,000,000 persons in the United States have heart disease and that the number of persons so afflicted not only has increased during the past two decades but is still on the increase.* The number of cases has been growing principally because of the general aging of the population and to a lesser extent because of the increase in the total population.

There are, furthermore, occupational differences in cardiac patients that reflect, in part, the physical demands and the mental stresses of various trades. It is not surprising that bartenders have the highest mortality from heart disease, but it is not especially comforting to learn that physicians are but slightly less vulnerable. In addition, it is difficult to understand why barbers, who apparently work no harder than physicians and are certainly under less mental strain, should die of heart disease only slightly less often than bartenders and at virtually the same rate as physicians. Perhaps the tonsorial art is truly arduous.

Apart from the question of whether heart disease as a whole is on the increase, one must take into consideration the types of cardiac disease from which people die, as well as the changing diagnostic criteria during the past twenty-five years. If this is done, one learns that deaths ascribed to chronic valvular disease have shown a steady and rather rapid decline whereas those due to disease of the coronary arteries have made a corresponding — and alarming — increase. It must, however, be remembered that the clinical diagnosis of coronary disease has only recently achieved its present accuracy, and yet autopsy figures tend to show that there is not only a relative but an absolute increase in the mortality rate from this type of heart failure.

Regarding prognosis, the death rate from chronic valvular disease in cases of rheumatic fever with no heart involvement during the first year after the attack is comparatively low, being only 25 per 1000 for boys. With cardiac involvement, the rate is materially higher, being 208 per 1000 for boys. In general it may be said that the death rates for boys and girls following rheumatic fever are approximately the same except that during the first year of illness — whether or not the heart is reported to be enlarged — the mortality among boys is considerably greater than that among girls. Although the immediate mortality of coronary thrombosis is close to 20 per cent, it is encouraging to learn that five years after the initial attack over 50 per cent of those so stricken are able to carry on their work on either a full-time or part time basis. The worst prognosis appears to be in cardiovascular syphilis, which, theoretically, at least, is preventable.

On the whole the picture is not entirely black, for if one corrects for the aging of the population one finds that the over-all mortality from cardiac disease is not materially higher than it was thirty years ago, and that there is little that can be done about growing old — whether that be good or bad.

DEATH

MORRILL — Herman A. Morrill, M.D. of Gardner, died on May 28. He was in his forty ninth year.
Dr. Morrill received his degree from University of Vermont College of Medicine in 1925.

*Armstrong, D. B., Bonnett, E. C. and Dublin, L. I. *Studies in Heart Disease*. 20 pp. New York: Metropolitan Life Insurance Company, 1946.

A HUNDRED YEARS AGO

At 10 o'clock, on Wednesday last, the Fellows of the Massachusetts Medical Society met for the transaction of the usual business. At 1 o'clock, Dr John Ware, of Boston, delivered the annual discourse, which was replete with wisdom and practical good sense. The dinner was served in Faneuil Hall. Not far from four hundred medical gentlemen dined as though they enjoyed the meal — Dr Henry Bryant suggests from Paris the possibility of a fatal result being one of the *remote sequelae* of the inhalation of ether — a fact, if such it proves to be, that has not been previously stated. He reports the case of a patient who died on the fourth night after operation, having presented no particular symptoms except pain in her back and a little crepitous rale in the lower part of her back, but no dullness on percussion. On examination, the lungs presented posteriorly a little hypostatic congestion, the bronchi were remarkably flaccid and slightly red. He suggests that if similar cases occur, attention should be directed to the lungs — A great deal has been said of late by the secular press about *ship fever*. The famine in Ireland has hurried the rapid tide of immigration into this country, bringing a famishing multitude, crowding the steerage of every packet and passenger vessel, on board of which many have suffered for want of food and even of water, while occupying filthy and unventilated apartments. A malignant and fatal fever has thereby been generated on board ship, of which many have died on the passage, while still more have been landed either already sick or so infected by the atmospheric poison that they soon develop it, in a form no less dangerous and fatal than that which has proved mortal on board the vessels which brought them hither. In the nature and character of this fever there is nothing new or peculiar, its type is found to vary, but a large majority of the cases are well characterized under the name of *typhus petechialis*. The conditions of recovery are cleanliness, pure air, with ventilated apartments and careful nursing. Medication of an active character is contraindicated — The *New York Medical and Surgical Reporter*, which has been published weekly in that city for a short time, has been discontinued. The *Boston [Medical and Surgical] Journal* is again alone in this country as a weekly visitant to the medical profession — Among the numerous readers of this journal, there must be many who have patients laboring under long-continued disease whom they would desire to send to the Saratoga Springs, but are deterred by the expenses. Many private houses charge only from \$4.00 to \$7.00 a week and there are three large and excellent establishments, which comprise all necessary comforts and conveniences and afford nearly as good tables as the most expensive hotels, where the charge for board and lodging is \$5.00 for a week. There are quite a number of houses which have

the sign "House Room" at the door. This implies that a party, containing one or more females, can be allowed lodging, room, bed, bedding and furniture, and permission to use the fire and cooking utensils of the family — all for \$1.00 a week to each individual — The Post Master, writing from Geneva, Coffee County, Alabama, says that among a population voting about eight hundred, and 1 Geneva containing about forty families, they cannot count *one doctor*. The village is on a stream navigable for steamboats, at the heart of navigation and in a cotton region — Died, Dr Collins, young and accomplished physician, of ship fever which was contracted in rendering voluntary professional assistance to Irish emigrants in the hospital — Extracted from the *Boston Medical and Surgical Journal*, June-July, 1947

MISCELLANY

NEW ENGLAND DIABETES ASSOCIATION

At the first annual meeting of the New England Diabetes Association, held at the Boston City Hospital on April 10 the following officers and directors were elected: president, Dr Elliott P. Joslin, vice-president, Dr W. Richard Ohle, secretary, Dr James H. Townsend, treasurer, Dr Helmut Ulrich, and directors — to serve for one year, Drs F. Gorham, Brigham, John Casey, David Hurwitz and Augustine Conroy; to serve for two years, Drs Howard F. Root, Alexander Burgess, Harry T. French and E. R. Blaisdell, and to serve for three years, Drs Frank N. Allan, George Ballantyne, Richard Stetson and Ellsworth L. Amidon.

The Board of Directors held a meeting on May 14 to consider plans for the future operation of the association. It was voted to hold two meetings a year, in addition to the annual meeting, one of which would be held outside of Boston. Committees were appointed to report on various problems concerning the welfare of diabetic patients. The following honorary members were unanimously elected: Drs Full Albright and George R. Minot and Miss Frances Stern.

At present the association comprises 105 active members and 3 honorary members.

It is anticipated that the next annual meeting of the association will take place in Providence during the first two weeks of November.

NOTICES

AMERICAN ASSOCIATION ON MENTAL DEFICIENCY

The First International Congress on Mental Deficiency will be held in Boston, at the Hotel Statler, on May 11, 13, 14 and 15, 1948. This meeting is to commemorate the first American institution for mental defectives, which was established in Boston in 1848. It is anticipated that there will be delegates and speakers from North and South America, the British Isles, Europe, Australia and New Zealand. The chairman for the Committee on Arrangements is Dr Stanley Raymond, of Wrentham, Massachusetts.

THE OPERATIVE TREATMENT OF DECUBITUS ULCER*

EDMUND J. CROCE, M.D.,† AND MAJOR CHARLES H. C. BEAKES, M.C., A.U.S.

SINCE the original report on the operative treatment of decubitus ulcer from this hospital,¹ considerable experience has been amassed, and a great impetus has occurred in this field in other Army hospitals. Most of the work has been done on paraplegic battle casualties.² The indications for the operative closure of decubitus ulcers in these patients no longer appear to be disputable. First and foremost, such a procedure effects, with little risk, a tremendous boost in the patient's morale and suddenly terminates the loss of tissue protein from the ulcer surface, thus favoring protein anabolism, increased appetite, strength, weight and general well-being.³ It also removes the stigma of dependency on frequent dressings and allows an unhampered progress in ambulation.

GENERAL CONSIDERATIONS

The present report comprises the entire program of the management of decubitus ulcers in 130 paraplegic patients treated at Halloran General Hospital over a fifteen-month period, beginning in April, 1945. In this group were 62 patients with sacral ulcers, of which 42 were operated on at this hospital. Sliding, full-thickness flaps were employed in 38 cases, and split-thickness grafts in 4. The ulcers had been closed at other hospitals in 3 cases, by a rotating pedicle flap in 1 and by split-thickness grafts in 2. One of the last proved entirely unsatisfactory and was excised and replaced by sliding flaps. The ulcers in the remaining 17 cases were allowed to heal by secondary intention, either because they were small and superficial or because they were almost completely healed when the patients were transferred to us.

There were 49 cases of trochanteric ulcer. Of these, 31 were closed at this hospital by sliding, full thickness skin flaps. Eight had been closed at other hospitals—4 by sliding flaps, 1 by a rotated pedicle flap, and 3 by split-thickness grafts. Two of these cases proved rather unsatisfactory because of repeated ulcerations, and one has already been excised and replaced by sliding, full-thickness flaps.

There were 9 cases of ulcer of the ischial tuberosity. Only 4 of these patients were operated on.

There were a number of miscellaneous ulcers in the following order of frequency over the calcaneus, dorsal spines, anterior superior iliac spines, fibular head, scapular spines, malleolus and patella. Only an occasional case was selected for operative closure—2 over the dorsal spine, 1 over the anterior superior iliac spine, 1 over the scapular spine, 1 over the patella, and 1 of the anterior chest wall.

The objectives of the program were twofold: to obtain an early and complete closure and to obtain a closure that would be stable and satisfactory. Although the first objective could be readily realized by the application of split-thickness grafts to the denuded areas, it was soon observed that the end results thus obtained were often unsatisfactory. These grafts, which were intimately adherent to the underlying osseous prominence, with only a thin layer of fibrous tissue intervening, ulcerated repeatedly in response to the unavoidable trauma of the denervated skin. The grafts served as an expedient to obtain the first objective in patients who were not ready for the more extensive procedure, but the second objective was not considered to have been achieved, and these grafts were sometimes replaced by full-thickness flaps at a later date.

The preparation of a patient for the major procedure of closure with full-thickness skin flaps must receive careful consideration. The larger the ulcer, the more extensive the dissection of adjacent skin area to mobilize the skin and to close the defect without tension. Some degree of shock is unavoidable, even with transfusion, in the closure of large ulcers. Consequently, debilitated patients should not be subjected to such major procedures. Furthermore, the healing powers of such patients are poor, and they have less resistance to infection. The average paraplegic casualty was found to have lost about 50 pounds in weight the first month after injury. During this period of rapid and severe catabolism, when the protein stores of the liver and muscles were seriously depleted, most of the decubitus ulcers appeared—a great many of them within a few hours or a few days after injury. Although the appearance of the ulcers over bony

†Assistant surgeon, Worcester City Hospital, Worcester, Massachusetts; formerly chief of Surgical Service, Halloran General Hospital.

prominences could in many cases be attributed to infrequent change of position and soiling during the rapid chain of evacuation from the front, in the last analysis it is likely that the skin is rendered more vulnerable to such traumas by the general catabolism, especially of proteins.³

Clinically, during this early phase, the appearance of the decubitus ulcer is characteristic. There is no

closed by the temporary expedient of application of a split-thickness graft, since in most cases the patient is not prepared systemically for a major procedure. Many patients did not arrive at our hospital until several months had elapsed, and they had therefore passed successfully through the initial phase. Few of them, however, had been detained in the chain of evacuation long enough for skin grafts

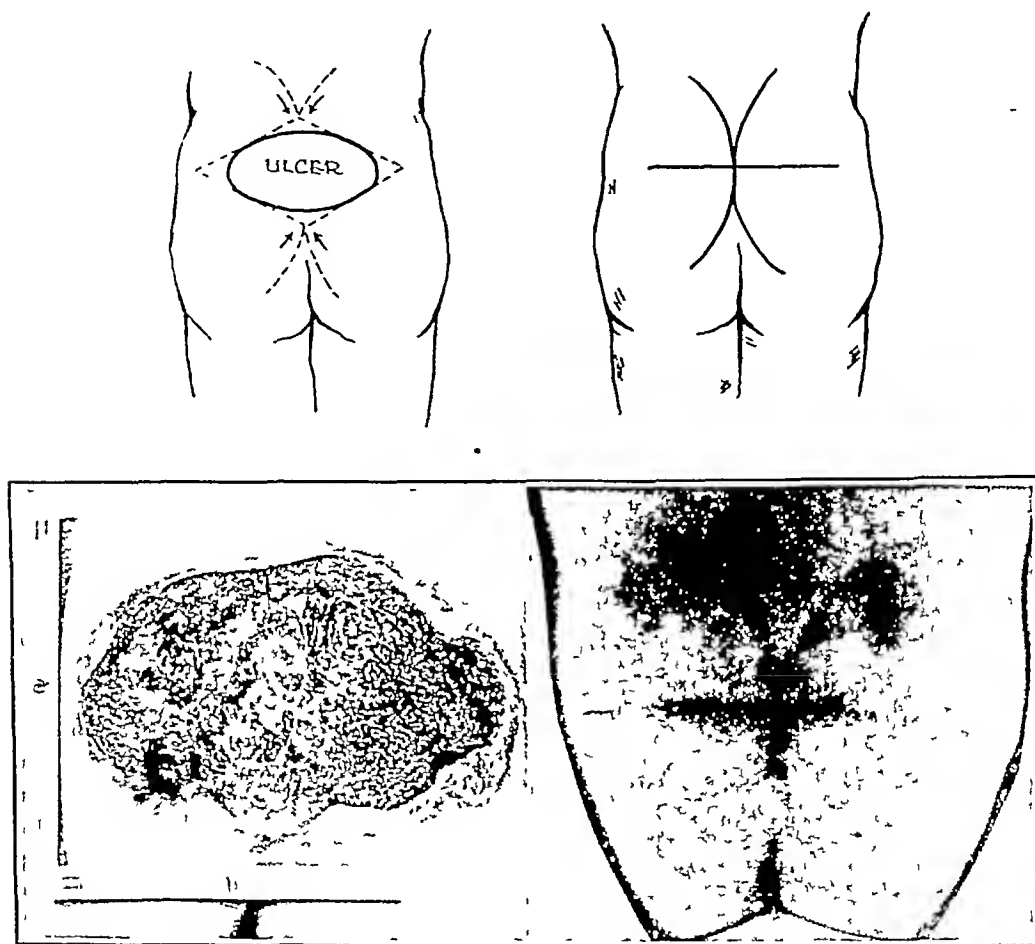

FIGURE 1 Transversely Oval Sacral Decubitus (Case 1)

evidence of healing process, but only of extending necrosis. The exudation of body fluids is profuse and thus, by a vicious circle, delays recovery. During this phase, treatment must be aimed at restoration of protein anabolism, forced oral feeding and parenteral alimentation with amino acids being used if necessary. Local infection must be controlled by conservative débridement of necrotic tissue and by systemic and local administration of chemotherapeutic agents. Anemia is controlled by repeated transfusions.

As soon as the local condition permits, as indicated by cessation of spreading necrosis, the appearance of healthy granulation tissue and the subsidence of active cellulitis, we believe that the ulcer should be

to be applied. The ulcers that most of them presented on admission were in the healing phase—that is, they were largely lined with a layer of granulation tissue, showed evidence of varying degrees of wound retraction and revealed only small areas of exposed nonviable or necrotizing fascia. Local acute inflammation had subsided, and exudation had materially decreased. The patients had already begun to regain weight and strength, they had passed the period of spinal shock, and automatic reflexes could be readily elicited. On admission, both aerobic and anaerobic cultures were taken routinely from ulcer surfaces. These cultures revealed a marked similarity to urinary and fecal flora, the following organisms being encoun-

tered *Proteus vulgaris*, *Escherichia coli*, *Aerobacter aerogenes*, *Pseudomonas aeruginosa*, *Staphylococcus aureus*, streptococcus and finally some of the Clostridia, usually of low pathogenicity. Other anaerobes were rarely found. On the basis of experience bacteriologic findings were, in general, disregarded although an attempt was made to protect the patient from invasive organisms by local dusting

dence of retraction from healing and finally showed invasion by a gray-white peripheral zone of proliferating epithelium.

Most patients required no anesthesia at the time of operation, since the ulcer occurred well below the sensory level. When anesthesia was required, endotracheal administration of ether was used almost exclusively, since it was considered safest

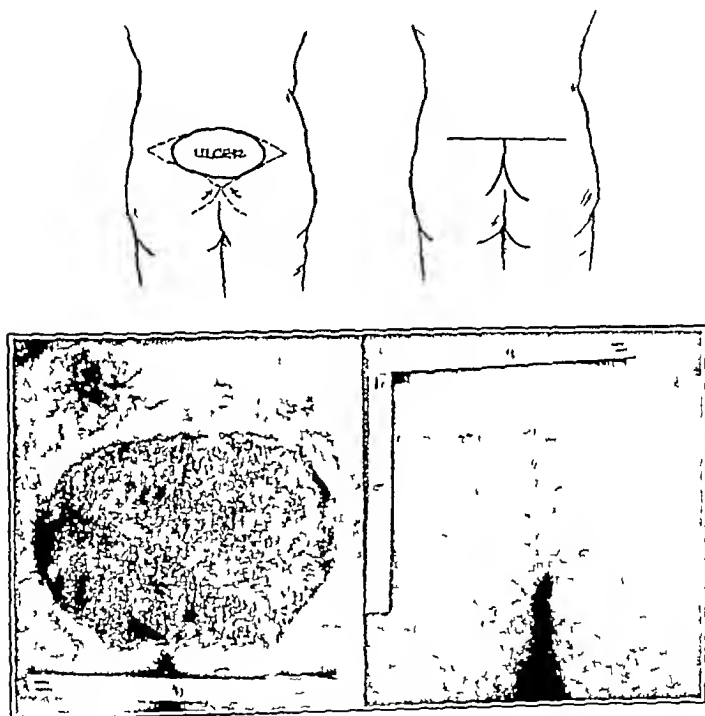

FIGURE 2. Transversely Oval Sacral Decubitus (Case 2)
The photographs show the appearances before and five weeks after operation

of the operative surface with plasma-penicillin powder and by the administration of penicillin for five days preoperatively and, when indicated by the presence of *Staph. aureus* or streptococcus, for several days after operation. In the selection of patients for the major operative procedure, more reliance was placed on the clinical appearance of the ulcer. An ulcer was considered ready for operation when it became free from all evidence of recent cellulitis, when it presented a healthy granulating surface, when all non-viable tissue had separated, when exudation had practically ceased and when the wound margins began to show evi-

dence of retraction from healing and finally showed invasion by a gray-white peripheral zone of proliferating epithelium. Continuous spinal anesthesia was rarely employed. When only the proximal part of the ulcer lay above the sensory level, this portion of the operative field was sometimes infiltrated with procaine. The general operative technic has been described in a previous paper,¹ but the following technical details should be re-emphasized: sharp dissection, excision of all scarred tissue, fine-silk hemostasis, the development of flaps sufficiently extensive to allow closure without tension, thorough irrigation of the operative-wound surface with physiologic saline solution before closure, followed by dusting with plasma-penicillin

prominences could in many cases be attributed to infrequent change of position and soiling during the rapid chain of evacuation from the front, in the last analysis it is likely that the skin is rendered more vulnerable to such traumas by the general catabolism, especially of proteins.³

Clinically, during this early phase, the appearance of the decubitus ulcer is characteristic. There is no

closed by the temporary expedient of application of a split-thickness graft, since in most cases the patient is not prepared systemically for a major procedure. Many patients did not arrive at our hospital until several months had elapsed, and they had therefore passed successfully through the initial phase. Few of them, however, had been detained in the chain of evacuation long enough for skin grafts

evidence of healing process, but only of extending necrosis. The exudation of body fluids is profuse and thus, by a vicious circle, delays recovery. During this phase, treatment must be aimed at restoration of protein anabolism, forced oral feeding and parenteral alimentation with amino acids being used if necessary. Local infection must be controlled by conservative débridement of necrotic tissue and by systemic and local administration of chemotherapeutic agents. Anemia is controlled by repeated transfusions.

As soon as the local condition permits, as indicated by cessation of spreading necrosis, the appearance of healthy granulation tissue and the subsidence of active cellulitis, we believe that the ulcer should be

to be applied. The ulcers that most of them presented on admission were in the healing phase—that is, they were largely lined with a layer of granulation tissue, showed evidence of varying degrees of wound retraction and revealed only small areas of exposed nonviable or necrotizing fascia. Local acute inflammation had subsided, and exudation had materially decreased. The patients had already begun to regain weight and strength, they had passed the period of spinal shock, and automatic reflexes could be readily elicited. On admission, both aerobic and anaerobic cultures were taken routinely from ulcer surfaces. These cultures revealed a marked similarity to urinary and fecal flora, the following organisms being encoun-

like extensions over the posterior superior spines, were closed by a modification of the first method, the upper sector flap being smaller than the lower (Fig 3)

There were 6 vertically oval ulcers, which were closed by elliptical vertical excision, with triangular extensions into each buttock (Fig 4)

Of the small sacral ulcers, only one was closed by rotation of a single flap upward from one buttock

the four flaps in 5 cases, but these were all 2 cm or less in diameter and healed uneventfully in a few weeks. There was only one frank wound infection, and this significantly occurred in the only case in which absorbable gauze was used for hemostatic purposes. The infection subsided promptly on removal of the foreign body. We do not desire to condemn the use of this gauze, but merely to caution against its use immediately underlying a

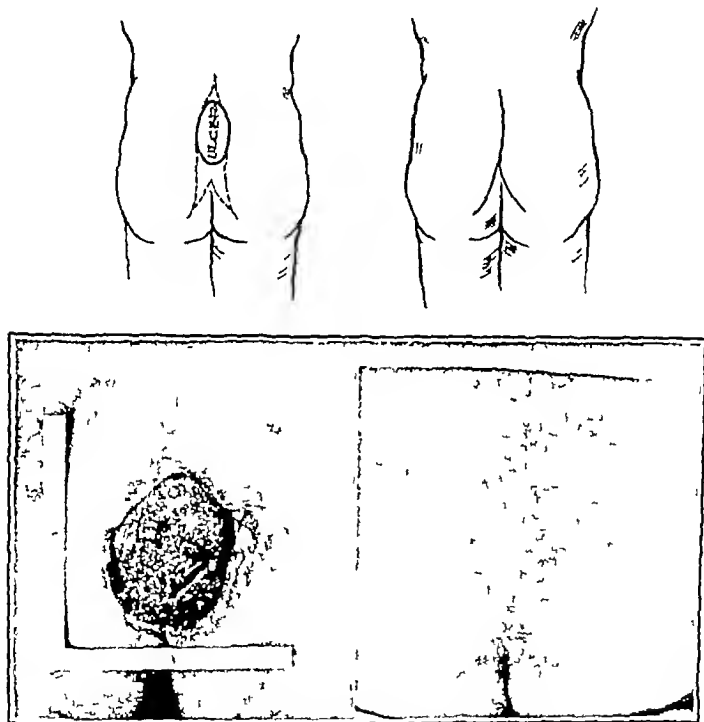

FIGURE 4. Vertically Oval Sacral Decubitus (Case 4)

The photographs show the appearances before and fourteen months after operation

(Fig 5) Although this method has been mentioned by other authors, it is not considered suited to the closing of large sacral ulcers

There were few serious complications. Only 1 patient developed a postoperative skin necrosis, resulting in a loss of an area 2 by 4 cm, which was surgically excised and successfully skin grafted. There were 2 cases of extensive wound disruption, but both healed by first intention on resuture. There were small dehiscences at the confluence of

suture line, particularly where there is a subcutaneous bony prominence. Sacral cases sometimes presented accumulations of sterile serous fluid that were treated by repeated aspirations. Drains were not used at any time in the entire series. One case developed a large hematoma underlying the flaps, and this was evacuated surgically.

Many of the sacral operations were performed more than a year ago. There have been few late complications. One patient developed an ischemic

necrosis of a portion of a postoperative flap three weeks after operation, owing to sitting in a wheel chair for six hours without a change of position. Another developed a secondary ulcer six months

ulcer would be a much more difficult accomplishment. An analysis of the situation discloses the nature of these difficulties. Thus, the skin is usually drawn tightly over the hip, so that more extensive

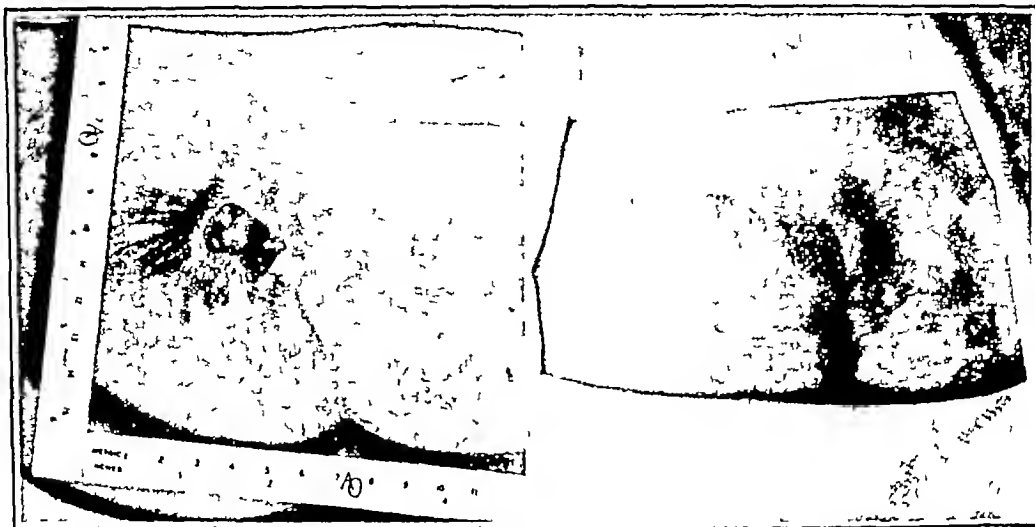

FIGURE 5 Small Sacral Decubitus (Case 5)

The photographs show the appearances before and eleven weeks after closure by rotating a single flap from the buttock

postoperatively, following immobilization for three days because of serious illness. The ulcers in both cases were closed by further advancing of the same flaps. These cases merely illustrate that the skin

dissection is required to cover relatively small defects. It is difficult to immobilize the hip without placing the patient in a plaster spica. Any motion of the hip — especially flexion and adduction, which

FIGURE 6 Small Trochanteric Decubitus (Case 6)

The photographs show the appearances before and three months after linear closure

must receive the same care postoperatively as the unbroken skin.

TROCHANTERIC ULCERS

From the beginning of the program, it was recognized that the successful closure of a trochanteric

are frequent in reflex spasms — tends to disrupt the repair of soft tissues over the trochanteric prominence. The superficial appearance of the ulcer generally belies its true extent, since there is usually considerable skin retraction about the ulcer and an extensive subcutaneous defect where the trochanter

has worn away the fascia lata to produce a so-called "false bursa."

A total of 49 cases of trochanteric ulcer have been observed in 43 patients. Thirty-one of these were operated on at this hospital. In 4 cases the ulcer had been closed before admission to this hospital. One of these had been closed by a rotating full-thickness flap, the donor site being covered by a split-thickness graft, this procedure proved quite

subsection, to raise a substantial anterior and posterior flap, usually allowed the approximation of these flaps without undue tension (Fig 6).

Single sliding flap. Trochanteric decubiti over 3 cm but less than 6 cm in the transverse diameter could usually be closed by the sliding of a semicircular flap from the corresponding buttock. The incision was usually continued from the inferior angle of the ulcer medially and posteriorly

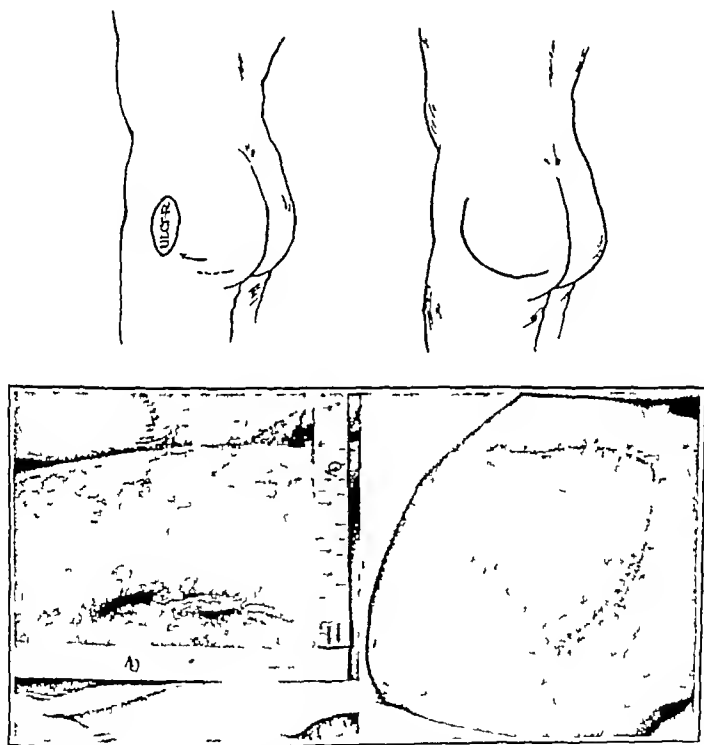

FIGURE 7 Trochanteric Decubitus (Case 7)

The photographs show the appearances before and four months after closure by the single flap method

satisfactory. The ulcers in 3 other cases had been closed merely by the application of split-thickness grafts, which proved rather unsatisfactory. One was finally excised and covered by a full-thickness flap. In general, the operative methods we employed fell into three groups.

Linear closure. Trochanteric ulcers are usually vertically oval. For those less than 3 cm in the transverse diameter, elliptical excision of all scar tissue along with the granulation tissue base and

along the inferior gluteal fold. A single large flap was developed and rotated laterally to cover the defect (Fig 7).

Double sliding flaps. Trochanteric ulcers over 6 cm in the transverse were closed by the development of an additional semicircular flap anteriorly and superiorly from the anterior surface of the thigh, thus creating an S-shaped wound on approximation (Fig 8).

In this series 5 patients were treated by linear closure, 20 by single sliding flaps, and 6 by double sliding flaps. In general the results were not so good as those in the management of sacral ulcers. Of the ulcers with linear closures, 3 healed by first intention, and 2 developed small dehiscences. Of the 21 single-flap closures, 13 healed by first intention, and 4 developed partial dehiscences. Three of

ischial regions were encountered with greater frequency. Most paraplegic patients have atrophic gluteal muscles, as a result of which they present a great deal of loose skin for the closure of sacral ulcers, but little padding for the ischial tuberosity. Clinically, these patients sometimes developed redness and swelling in the ischial regions. At first these lesions were often mistaken for early ischial

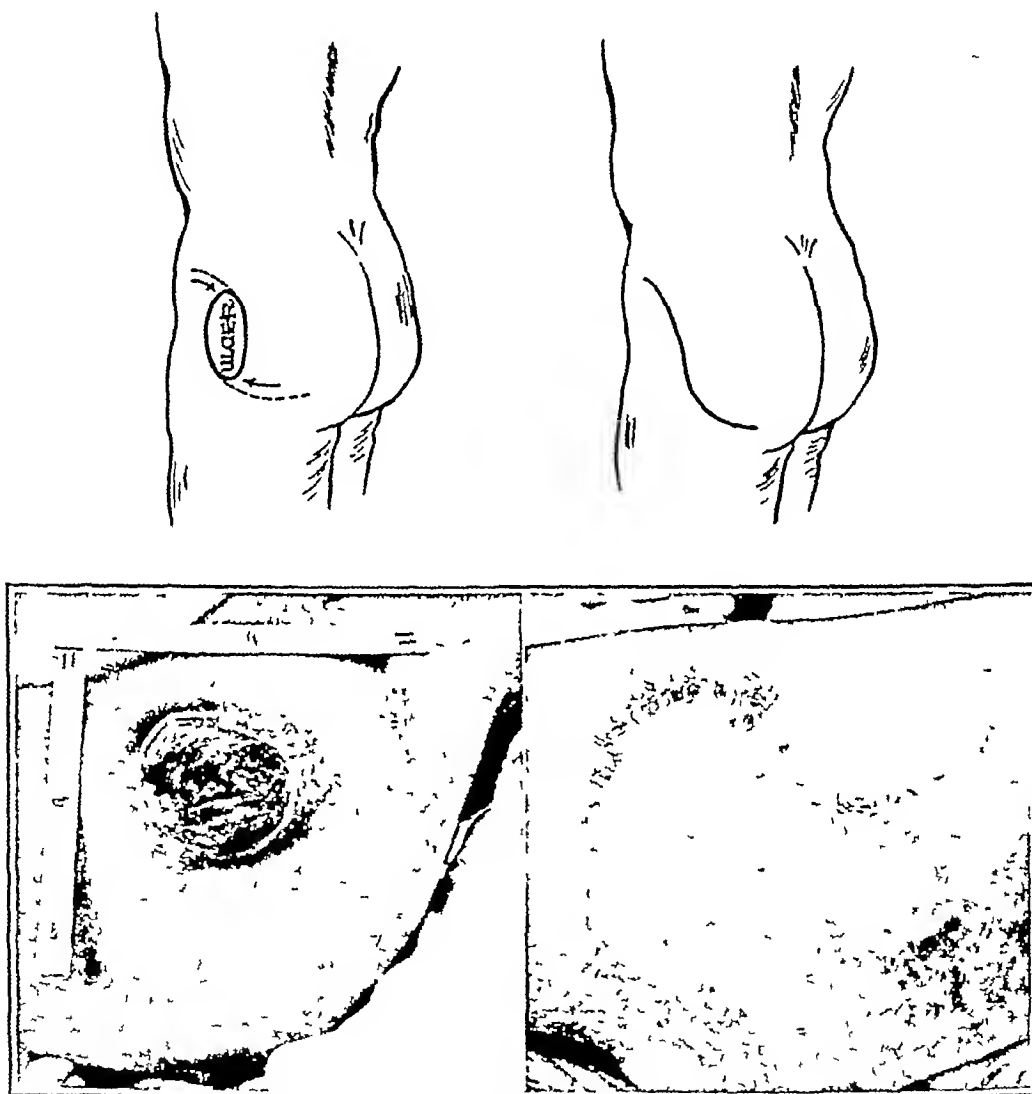

FIGURE 8 Trochanteric Decubitus (Case 8)

The photographs show the appearances before and two months after closure by the double-flap method

the latter patients were severely spastic, and another was undernourished and failed to heal any of his operative wounds. It is believed that postoperative immobilization in a padded plaster spica, with the hip abducted, will improve the results in this type of surgery.

ISCHIAL DECUBITUS

As the program of rehabilitation of paraplegic patients progressed and more of them left their beds for the wheel chairs, various lesions of the

abscesses, but it was soon discovered that incision led to the formation of sinuses communicating with chronically infected ischial bursas, curable only by excision of the bursa. Preferably, the early treatment consists of cessation of weight bearing and systemic chemotherapy. The signs of inflammation usually subsided slowly with this regime. Once the superficial tissues have ulcerated over the ischial tuberosity, however, the ulcer is best treated surgically by excision and linear closure. So important is complete immobilization in the postoperative treat-

ment of these lesions, that we have come to rely on oothog short of the well padded plaster spica. Of the 4 patients operated on, 2 with ulcers that healed by first intention were thus treated

MISCELLANEOUS TYPES

A relatively frequent decubitus that continues to challenge the surgical program is that over the calcaneus. From our own experience and that of others, it was concluded that split-thickness grafts would be undesirable. Local closure with full-thickness sliding flaps was also not feasible, and pedicle flaps from the thighs were considered impractical. The patients were therefore treated by nonoperative methods and not allowed to delay ambulation.

In the closure of dorsal ulcers, it seems advisable to resect the protruding spinous process before closure.

SUMMARY AND CONCLUSIONS

The treatment of large decubitus ulcers in a young paraplegic patient is a surgical problem.

The more frequent varieties of decubitus ulcer — sacral, trochanteric and ischial — may be closed by sliding full-thickness skin flaps. Surgical experiences in performing such closures on a large number and variety of ulcers are reported. The important details of these procedures are presented.

Full-thickness skin closure of decubitus ulcers gives a much more satisfactory result than either secondary healing or closure with split-thickness graft. The procedure is sometimes a relatively formidable one, and is not recommended for the closure of decubitus ulcers in the aged and debilitated.

WOUND INFECTIONS WITH FRIEDLÄNDER BACILLUS FOLLOWED BY MENINGITIS

SAUL SOLOMON, M.D.*

NEW YORK CITY

THE Friedländer bacillus (*Klebsiella pneumoniae*), under the right conditions, is highly virulent for man. Hence, although infections with this organism are not frequent, they deserve consideration out of proportion to their incidence. Appreciation of this fact is essential so that cases may be recognized and treated early with methods now in use and also in order that new and more effective remedies may be developed. With this in mind, 3 cases of wound infection with Friedländer bacillus, followed by fatal meningitis, are presented below.

There are surprisingly few reports in the literature containing careful bacteriologic studies of wound infections and only a few bare references to the role of the Friedländer bacillus. Riggenbach¹ was perhaps the first to report a case of wound infection due to the organism. Levaditi,² reporting on wound infections in World War I, mentioned that the organisms most generally found were staphylococci (in 85 per cent of cases), Friedländer bacillus, *Clostridium welchii*, streptococci, the coli group and *Pseudomonas aeruginosa*. Pulaski, Meleney and Spaeth³ found that staphylococci could be recovered from nearly every wound. Streptococci were isolated from half the wounds. Gram-negative organisms, such as *Escherichia coli*, *Proteus vulgaris*, *Eberthella typhosa*, *Pseudomonas aeruginosa* and *K. pneumoniae*, were found in

a fourth of the cases. Among the numerous other reports on wound infections there is to my knowledge no mention of the Friedländer bacillus. The First General Medical Laboratory, which received a fair sampling of cultures from United States Army hospitals in the United Kingdom, informed me in October, 1944, that within several weeks they had identified the bacillus in wound cultures in 6 cases. It is my impression that if careful cultures of wounds were done routinely, the bacillus would be found quite frequently. Its seeming rarity in wound infections may also be explained in part by the tendency to pass off all gram-negative rods found in wound cultures as coliform organisms.

Meningitis due to Friedländer bacillus is apparently rare. In 1938 3 cases secondary to pneumonia were reported.⁴ Ransmeier,⁵ in 1943, reported 1 case and referred to 29 others in the literature. In approximately half the cases the meningitis followed infections of the middle ear or sinuses. In the remainder it followed pneumonia, cholecystitis or colitis with bacteremia. None of the cases were related to trauma. Hence the finding of 3 cases of meningitis due to Friedländer bacillus following war wounds seems worthy of reporting.

BACTERIOLOGIC

The organism is a gram-negative rod, 0.5 to 5 microns in length and approximately half as wide

*Assistant clinical professor of medicine, New York University; adjunct professor of medicine, New York Polyclinic Medical School and Hospital; locum tenens physician, Bellevue Hospital; formerly, Lieutenant Colonel, A.C. A.U.S.

Consequently, it may be either quite long or coccoid in shape. It may be seen singly or in short chains. It is nonmotile, nonspore forming, aerobic and facultative anaerobic. It has a distinct, thick capsule, which is seen on direct smears from infections with the organism. The organism grows readily in the usual laboratory mediums. On solid mediums the colonies are large and opaque and have a slimy, mucoid appearance.

Julianelle⁶ identified several distinct types by means of agglutination and animal protection tests. These are groups A, B and C, as well as a heterogeneous group known as "X." The distinction between the different types depends on chemical differences in the polysaccharide of the capsule. The organism has a rather wide distribution, being found in the soil, air and water. It also occurs as a saprophyte in the upper respiratory and intestinal tracts in a small percentage of normal human beings.

Infections due to the bacillus may be conveniently divided into pulmonary and extrapulmonary groups.

PULMONARY INFECTIONS

Approximately 1 to 3 per cent of all pneumonias are due to *K pneumoniae*. This form of pneumonia is most virulent, but many cases run a course with a temperature below 101°F.⁴ The pneumonia is lobar in character, but involvement of several lobes is frequent. The sputum, in the majority of cases, is a characteristic homogeneous emulsion of blood and mucus—brick red in color and unlike the prune juice sputum of pneumococcal pneumonia or the bloody sputum often found with tuberculosis. A direct smear shows many large, gram-negative encapsulated bacilli. The organism can be recovered in pure culture by mouse inoculation or by culture of the sputum on blood-agar plates. Bacteremia occurs in the majority of cases but is ordinarily not intense. The most frequent complications are abscess formation and empyema, meningitis and purulent pericarditis occur more rarely. The mortality in untreated cases is over 90 per cent.

Chronic lung infections due to this organism are less frequent and are often misdiagnosed.⁷ Non-putrid lung abscesses are frequent, and these are usually located in one or both upper lobes. Hence, the disease is often mistaken for pulmonary tuberculosis unless the case is critically evaluated. It is by no means easy to find the organism in the chronic stages, since secondary invaders may overgrow it.

EXTRAPULMONARY INFECTIONS

These have been described in detail by Baehr, Schwartzman and Greenspan⁸ and more recently by Jaffe.⁹ Intra-abdominal infections are usually secondary to perforative lesions of the large intestine, such as appendicitis, diverticulitis and carcinoma. Abscess formation or generalized peritonitis may occur. Secondly, subphrenic or liver abscess and, occasionally, septicemia may result. Biliary-

tract infections, which are next in frequency, usually occur in association with gallstones. Purulent otitis media and mastoiditis are not rare and may lead to cavernous sinus thrombosis or meningitis.

It is of interest that extrapulmonary infections generally have a relatively low mortality (17 to 20 per cent). The mortality in cases complicated by bacteremia is about 75 per cent, and that in meningitis is over 90 per cent.

TREATMENT

Specific horse antiserum has been used with varying results. Bullock, Chess and Friedman¹⁰ reported a reduction of mortality in pneumonia due to Friedländer bacillus, but my own experience with antiserum was disappointing.⁴

In recent years the sulfonamides have been used with some success. I⁷ first employed sulfapyridine in 1938 in the treatment of 4 cases. The patients survived, although they developed the chronic form of the disease. More recently, Feinstein and co-workers¹¹ showed that in experimental infection in mice, sulfadiazine is superior to other sulfonamides, and clinical reports have described these results. Appelbaum¹² noted recovery in a fair percentage of cases of meningitis treated with sulfonamides and, more recently, in a case treated with streptomycin. Penicillin has not been found effective.^{13, 14} In Cases 1 and 2 reported below, the organism was resistant in vitro to concentrations of penicillin as high as 1000 units per cubic centimeter—levels that are impossible to attain in the blood stream. More hopeful, however, is recent experimental work by Heilman,¹⁵ which indicates that streptomycin may have definite value.

CASE REPORTS

CASE 1. A 26-year-old soldier was wounded in France on August 8, 1944, by mortar-shell fragments, sustaining penetrating wounds of the left buttock and a fracture of the ilium. He received treatment in a field hospital and was evacuated to England on August 20.

The wound of the left buttock showed a mucopurulent discharge, and treatment with sulfadiazine was instituted (1 gm every 4 hours). On August 24 the temperature rose to 104°F, the neck was stiff, and Kernig's sign was positive. Cultures from the wound and blood were positive for *Typ K pneumoniae*. A spinal tap yielded a cloudy fluid containing 5200 polymorphonuclear cells per cubic millimeter, the sulfadiazine level was 3.8 mg per 100 cc. A direct smear of the sediment showed many gram-negative, encapsulated bacilli. Examination of the blood showed a white-cell count of 14,800, with 82 per cent segmented neutrophils, 8 per cent young forms and 10 per cent lymphocytes.

Treatment with penicillin was started at 4 p.m., the patient receiving 30,000 units intravenously, followed by 30,000 units intramuscularly every 4 hours. At 6 p.m. 5 gm of penicillin was given intrathecally, followed by 5 gm of sodium sulfadiazine intravenously. The temperature rose to 107°F at 10 p.m. Analysis of the spinal fluid showed essentially the same findings, except that the sulfadiazine level was 9.3 mg per 100 cc, 5000 units of penicillin was instilled intrathecally. The patient did not respond to therapy and died at 9 o'clock on the following morning.

Autopsy. Post-mortem examination disclosed greenish-yellow pus covering the entire brain and spinal cord. The choroid plexus contained a number of small collections of pus. Careful examination of the spinal cord revealed tear of the meninges.

Dissection of the wound of the left hip demonstrated a severe destructive process involving the deep muscles. The internal and middle ears appeared normal. Cultures from the meninges, the blood and the wound showed a pure growth of *K. pneumoniae*.

Case 2. A 19-year-old soldier was wounded by shell fragments on August 13, 1944 sustaining a scalp wound and fracture of the skull. He did well and was evacuated to England on September 6. The general condition was good, but the wound exuded some serous material. Roentgenograms of the skull showed several indriven bone fragments near the falx and a metallic foreign body at the base of the skull.

Operation was done for depressed skull fracture on September 9 devitalized brain and free bone fragments being removed. Two days later the patient developed signs of meningitis. A spinal tap yielded a purulent fluid that contained Friedländer bacilli in pure culture. The patient was treated intensively with sulfadiazine and penicillin intramuscularly and intrathecally but showed no response death occurring on September 13.

Autopsy. Post mortem examination showed the brain to be covered by a massive exudate of fibrin and pus that contained many encapsulated bacilli. A brain abscess was seen in the hypothalamus in the center of which a metallic foreign body was found.

Most of the left lung was consolidated in the stage of red hepatization. Culture of the wound, the abscess, the meninges, the left lung and the blood showed *K. pneumoniae*. It is of interest that the abscess had remained quiescent for 4 weeks before it ruptured leading to septicemia and meningitis.

Case 3. A 29-year-old soldier was wounded by shell fragments on September 9, 1944 sustaining penetrating wounds of the abdomen, with perforation of the jejunum and descending colon. He also suffered a deep laceration over the sacrum with fractures of the left transverse processes of the 3rd, 4th and 5th lumbar vertebrae. This was followed by left foot drop. The jejunal perforations were sutured and a colostomy was done at a field hospital. The patient received a blood transfusion, 20,000 units of penicillin and some sulfadiazine (quantity not stated) and was evacuated to England on September 28.

The temperature ranged from 99 to 102°F. He became restless and irrational. On October 1 a spinal tap yielded a milky fluid containing 90,000 polymorphonuclear per cubic millimeter. Gram negative encapsulated bacilli were seen in the smear and culture showed *K. pneumoniae*. Death occurred on the same day.

Autopsy.* Post mortem examination revealed the laceration over the sacrum to extend into a large abscess 12 cm in diameter. The dura and several fibers of the cauda equina on the left were lacerated, and beneath the pia a greenish purulent exudate was noted. A similar exudate was found over the cortex and base of the brain. The sinuses and middle ear were normal.

A small amount of green pus was expressed from around the apparently closed colostomy. The lungs showed several infarctions in both lower lobes and an embolus in one of the branches of the left pulmonary artery.

Culture of the heart's blood was negative; culture from the brain from the area about the colostomy and from the laceration in the sacral region showed *K. pneumoniae*.

The laceration of the sacral region involving the dura and cauda equina was apparently the site of an unrecognized Friedländer bacillus infection that had gained entry into the subarachnoid space resulting in meningitis.

DISCUSSION

The patients in the cases presented above sustained shell-fragment wounds complicated by meningitis, but the pathogenesis of the meningitis was different in each case. In Case 1 the wound infection was followed by bacteremia and meningitis. In Case 2 there was a brain abscess around a shell

fragment. The abscess ruptured, resulting in meningitis and septicemia with death on the thirty-first day. The patient in Case 3 sustained lacerations of the sacral region and of the spinal dura. The wound was the site of *K. pneumoniae* infection that had extended directly through the torn dura leading to meningitis and death twenty-two days after injury. The organisms in Cases 2 and 3 were not typed, but their virulence and the finding of positive cultures in the blood and the meninges are presumptive evidence that they were Friedländer bacilli and not mucoid coliform organisms.

The origin of the Friedländer bacillus is in doubt. It is possible that the shell fragments carried the organisms into the tissues, but it is likelier that, in at least 2 of the cases, infection occurred during the period of hospitalization. This may have been due to fecal contamination, but since the organism is a frequent inhabitant of the upper respiratory tract it seems probable that the wounds became infected when dressings were changed. The wearing of masks by attending personnel and the strict observance of operating-room technique during routine dressings of wounds are often not practiced.

There were no features in the appearance of the wounds or in the clinical course that distinguish these cases from other wound infections. Such a differentiation could be attained only by routine bacteriologic study of infected wounds. Cultures were not made until an unusual complication had occurred. This was unfortunate because for some reason in each case a long latent period between the time of injury and the development of meningitis would have provided more time for treatment had the diagnosis of infection with Friedländer bacilli been made earlier.

The patient in Case 1 received adequate sulfadiazine therapy, but this did not prevent the development of bacteremia and meningitis. The addition of penicillin to the treatment after these complications had ensued had no effect. The second case was not diagnosed until forty-eight hours before death. Intensive therapy with penicillin and sulfadiazine had no effect. The patient in Case 3 was not given therapy for the infection.

SUMMARY

Three fatal cases of wound infection with Friedländer bacillus followed by meningitis are reported. Meningitis in one case was secondary to bacteremia, in another, it was due to direct extension through the torn dura of the spinal cord, and in the third it followed rupture of a brain abscess surrounding a metallic fragment.

The origin of the wound infections is in doubt, although it seems likely that they represented cases of hospital infection, and the most important factor in hospital infection of wounds appears to be droplets from the nose and throat. Hence, the need for the

*Performed by Lieutenant Colonel Jerome I. Silverman, chief of the laboratory of the One Hundred and Twenty Third General Hospital to whom I am indebted for permission to publish this case.

wearing of masks by attending personnel and for the observance of strict operating room technic when wounds are dressed should be emphasized

Routine culture of wounds should be made as soon as infections are apparent. In this way the physician will have precise bacteriologic data and will be able to start treatment at once. Treatment with sulfadiazine and penicillin was unsuccessful in 2 cases. It would be rash to draw any conclusions from this, but on the basis of past experience and of reports in the literature, sulfadiazine appears to be the most effective agent in use at present. Newer antibiotics, such as streptomycin, give promise of greater effectiveness and should be given further experimental and clinical trial. In infections with such a virulent organism, however, no remedy will prove generally effective unless bacteriologic diagnosis is made early.

ADDISON'S DISEASE ASSOCIATED WITH AMYLOIDOSIS FOLLOWING THERMAL BURNS*

Report of a Case

S. M. LEVENSON, M.D.,† H. J. TAGNON, M.D.,‡ W. L. GOODPASTER, M.D.,§ R. W. GREEN, M.D.,¶ F. H. L. TAYLOR, M.Sc., Ph.D.,|| AND C. C. LUND, M.D.**

BOSTON

ADDISON'S disease associated with amyloidosis of the adrenal glands is uncommon, less than 20 cases having been reported. Amyloidosis of the adrenal glands accounted for about 2 per cent of the cases of Addison's disease reported by Guttman.¹ Amyloidosis following thermal burns has rarely been reported,² and Addison's disease associated with amyloidosis following burns has not been reported to our knowledge. The following case presented such a combination.

A 42-year-old Negress with a noncontributory past history was admitted to the hospital May 10, 1944, with flame burns involving 15 per cent of the body surface, chiefly deep,

and severe thermal respiratory-tract injury. Eighteen hours after admission a tracheotomy was performed because of marked stridor and air hunger. There were no further respiratory difficulties, the tracheal tube being removed on the 10th day.

The surface burns were dressed initially with dry, sterile, pressure dressings without anesthesia or preliminary cleansing. Subsequent dressings were, for the most part, also dry-pressure dressings.

During the first 6 weeks the temperature varied between 100 and 102°F. Sulfadiazine, in doses of 6 gm. a day had been started on entry and was continued for 1 week. Following this 15,000 units of penicillin was given intramuscularly every 3 hours for 6 weeks. There were no toxic reactions to either drug.

Intravenous infusions of Amigen* were started on the day after entry and during the first 2 weeks constituted the chief protein nutriment, 3000 cc. being given daily. During that time the patient appeared to be in apparent positive nitrogen balance and to be maintaining her weight. The plasma protein concentration, however, fell from 7.2 gm. per 100 cc. of plasma on entry to 6.3 gm., and the albumin from 4.2 to 2.8 gm. Oral administration of 225 mg. of ascorbic acid, 9 mg. of thiamine chloride, 6 mg. of riboflavin, 60 mg. of nicotinamide, 15,000 units of vitamin A and 3000 units of vitamin D was given daily, as well as 15 cc. of crude liver extract (Wilson) intramuscularly.

During the 3rd week the intravenous infusions of Amigen were omitted, and the patient went into negative nitrogen balance, the intake having fallen to 6 gm. of nitrogen and 1600 calories daily. The vitamin intake remained the same. The plasma protein concentration, however, remained unchanged. By the 5th week, with urging and special nursing care, the intake was gradually raised to 40 gm. of nitrogen and 3500 calories daily, with dried beef serum as an oral supplement to the diet. The patient again appeared to be in

positive nitrogen balance. The beef serum supplement was continued for 8 weeks. The vitamin intake was unchanged.

The hemoglobin which had been normal on admission fell to 55 per cent by the 5th day and remained between 55 and 60 per cent until the 7th week. Thereafter sufficient type-specific whole blood transfusions were given to maintain the hemoglobin between 80 and 95 per cent. In the 7th week skin grafting of part of the burned area by the Padgett dermatome technique was done for the first time and was repeated in the 8th and 11th weeks. The takes of the graft were good but the donor sites failed to epithelialize in the next 5 weeks. During this period the food intake declined and the patient lost weight and strength. The vitamin supplements were not changed. The temperature varied between 98 and 100°F.

In the 5th and 6th months, under a regime of special nursing care and forced feedings consisting chiefly of milk with added milk powder, sugar and Amigen, the patient's condition improved markedly. The vitamin intake remained the same. She gained weight and strength and was getting out of bed. The plasma protein and albumin concentrations, which had fallen to 5.4 and 2.4 gm. per 100 cc. respectively at the 8th week rose to 7.5 and 3.1 gm. respectively. The tempera-

ture the level 2 hours after the injection of the insulin was significantly low, the fasting level being 98 mg. and the 2 hour level 24 mg. per 100 cc. On the 9th and 56th days, reactions were normal.

The urine, which since entry had shown albumin and white cells began to show large numbers of red cells in the sediment on occasional days during the 11th month. No casts were seen. The specific gravity of the urine became fixed at the end of the 12th month at 1.010. Urea clearance and phenolsulfonphthalein excretions were low. The non-protein nitrogen concentration in the plasma, which had been normal on entry and for the next 11 months rose to 49 mg. per 100 cc. In the 12th month (Table 1) and then rose slowly reaching a level of 75 mg. per 100 cc. by the end of the 12th month. The urine was negative for tubercle bacilli by the guinea pig technique, and a catheterized specimen was negative for other bacteria.

The blood pressure, which had been about 120/80 on entry, dropped to 105/70 by the 9th month and to 90/60 by the 12th month. The weight at that time was 90 pounds, as compared with an estimated weight of 125 pounds on entry. The granulations were still friable and grafting could not

*Diagnosis of Addison's disease in crisis, made at this time and adrenocortical extract, desoxycorticosterone, testosterone and sodium chloride therapy begun.

†Hormonal treatment discontinued.

‡Hormonal treatment resumed.

ture was normal and the donor sites had almost completely epithelialized.

From the seventh month on it was not possible to keep the patient on special nursing care. The food intake and general condition gradually deteriorated. In the 7th and 8th months 15,000 units of vitamin A, 3,000 units of vitamin D, 725 mg. of ascorbic acid, 9 mg. of thiamin, 6 mg. of riboflavin and 1.5 cc. of crude liver extract (Wilson) were given daily. In the 9th month through the 12th month the patient received in addition 2 cc. of halibut liver oil with viosterol (Parke-Davis). Thereafter, the fat soluble vitamin supplements were omitted, and she was given 500 mg. of ascorbic acid, 15 mg. of thiamin, 20 mg. of riboflavin and 150 mg. of nicotinamide daily. Loss of strength and weight were marked. The donor sites and some of the grafted areas broke down. The granulations became exuberant and friable. The fever was low grade. Cultures of the wounds throughout the course showed hemolytic *Staphylococcus aureus* as the predominant organism, with alpha hemolytic and beta hemolytic streptococci, diptheroids and *Proteus vulgaris* also present in the majority of cultures.

In general the white-cell counts were elevated the majority being about 15,000 with occasional extremes of 8,000 and 30,000. The leucine index throughout was 4. Cephalin-flocculation, hippuric acid, bromsulfalein and Quick prothrombin determinations were made on several occasions during the first 7 months and were always within normal limits.

Intravenous glucose-tolerance tests demonstrated a significantly elevated blood glucose concentration 2 hours after the injection of 25 gm. of glucose on the day of entry but a normal level on the 8th day. Intravenous insulin tolerance tests were done on the 1st, 9th and 56th days. On the 1st

day the patient was weak but alert. In the 13th month she became irrational and stuporous for a period of 6 hours following the administration of 0.1 gm. (1 1/2 gr.) of Nembutal. She had previously received this dose of Nembutal on many occasions without any untoward reaction. On the next day a dressing was done under cyclopropane anesthesia without preliminary medication. Following this she became delirious. The blood pressure fell to 85/40. On the following day she had an epileptiform seizure and became comatose. The blood pressure had fallen to 70/40 and the pulse was rapid and thready; the extremities were cold and clammy and the temperature 97°F. by rectum. The plasma nonprotein nitrogen had risen to 118 mg. per 100 cc., the chloride and the sodium which had been normal, had fallen to 68 and 128 milliequivalents per liter respectively. The carbon dioxide combining power on the next day was 13 millimoles per liter—it had been normal on entry. Pertinent laboratory data during the hospital course are presented in Table 1.

The diagnosis of Addison's disease in crisis was made by one of us (H. T.) and therapeutic measures were accordingly taken. Plasma and glucose in isotonic saline solution were given intravenously in the next hour. This produced a slight rise in the blood pressure to a level of 90/50 and a lowering of the pulse rate to 88. Immediately thereafter a regime of adrenocortical extract, desoxycorticosterone, testosterone propionate and additional intravenous saline solution and glucose was begun.

During the 1st day 50 cc. of adrenocortical extract, 35 mg. of desoxycorticosterone and 50 mg. of testosterone were given and 25 gm. of sodium chloride and 300 gm. of glucose were administered intravenously in the form of 10 per cent glucose in isotonic saline solution. Within 12 hours the patient had regained consciousness and had no further epileptiform

seizures. The blood pressure had risen by the following day to 110/50, and she was talking coherently. The rectal temperature had risen to 99°F. The blood sugar was normal. On the 2nd day 5 mg of desoxycorticosterone and 30 cc of adrenocortical extract in divided doses were given. The sodium and glucose intakes were about the same as on the previous day.

During the next 2½ weeks the patient received 25 mg of testosterone and 5 mg of desoxycorticosterone daily. She was given 2000 cc of Amigen with 300 cc of 50 per cent glucose intravenously daily, and was eating well. She appeared to be definitely improving. The blood pressure varied between 95/55 and 100/65. The nonprotein nitrogen had fallen to 60 mg per 100 cc, and the chloride had risen to

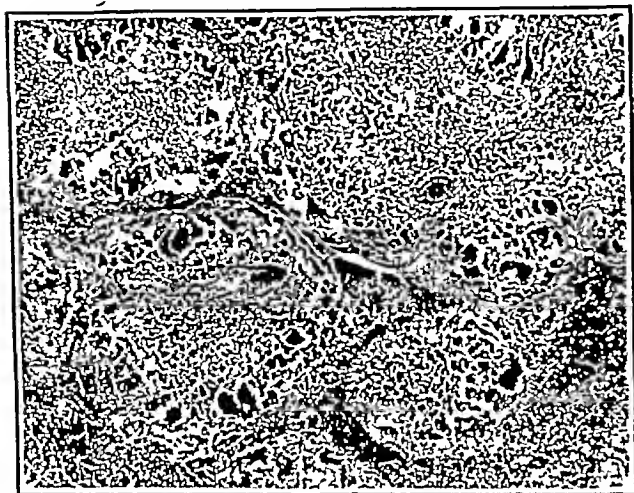

FIGURE 1 *Photomicrograph of Spleen Showing Marked Deposition of Amyloid*

100 and the sodium to 136 milliequiv per liter, the carbon dioxide combining power was 22.3 millimols per liter, and the lactic acid was 2.8 mg and the phosphate 5.7 mg per 100 cc. The plasma reaction was pH 7.38.

During the next 2 weeks no desoxycorticosterone or testosterone was given, but Amigen and glucose were continued. Ankle edema appeared for the first time, and vomiting began. The nonprotein nitrogen rose to 116 mg per 100 cc, and the blood pressure fell to 84/44. Adrenocortical extract, desoxycorticosterone and testosterone were resumed. During the next 24 hours, however, the patient gradually became more and more dyspneic and began to have definite air hunger. It appeared to most observers that she was having tracheal obstruction at the site of the tracheotomy scar rather than dyspnea secondary to acidosis. Consequently, tracheotomy was repeated, with some transient relief. No definite obstruction was found at operation. The nonprotein nitrogen had risen to 143 mg per 100 cc, the chloride had fallen to 87, and the sodium to 130 milliequiv per liter, and the carbon dioxide to 13 millimols per liter. The blood pressure fell further to 70/30. The patient died 12 hours later.

Autopsy. Post-mortem examination was performed 14 hours later. The body was that of a well developed, thin Negress. Scattered areas of granulation tissue were present on about 2 per cent of the body surface. The most striking findings were in the spleen, liver, kidneys and adrenal glands.

The spleen weighed 240 gm. It was firm, and the cut surface was pale rose in color and dotted with pale, translucent areas about 1 mm in diameter. The architecture of the spleen was markedly altered. With the lowest magnification a section appeared to be composed almost completely of a homogenous red substance, with only scattered small zones of remaining splenic pulp. Under higher magnification, the red areas were seen to be malpighian corpuscles largely replaced by amyloid (Fig 1), a splenic artery being found with each area. This substance was arranged in irregular

masses and gave a positive reaction for amyloid when stained with Congo red.³ Isolated cells and small groups of cells, consisting of lymphocytes and rarely red cells and polymorphonuclear leukocytes, lay between the masses of amyloid. The wall of the arterioles usually merged imperceptibly with the surrounding amyloid. In the areas of remaining splenic pulp, numerous red cells, a slightly increased number of polymorphonuclear leukocytes and macrophages containing golden yellow pigment were found. The walls of sinusoids and small arterioles and trabeculae were widened and appeared red and acellular, being composed principally of amyloid.

The liver weighed 1925 gm. The liver was congested and edematous and contained some amyloid. The degree of amyloidosis, however, was considerably less than that in the spleen and varied from section to section. Amyloid was found in the walls of small arterioles and larger arteries of the periportal areas. In widespread areas amyloid was found lying as large homogenous red masses between the sinusoidal lining and the hepatic cells. The hepatic cells were compressed in some areas. Amyloid was also found in the walls of large veins, lying just below the endothelium. The bile ducts were not involved. In areas not involved with amyloid the sinusoids were widened and filled with blood, and the liver cords compressed. Edema was suggested by the presence of a narrow space between Kupfer's lining and hepatic cells, pink granules were visible within this space in some places.

FIGURE 2 *Photomicrograph of Kidney, Showing Widespread Deposition of Amyloid*

The combined weight of the kidneys was 400 gm. The capsules stripped easily from a smooth surface. The cortices were mottled purple and yellow and measured 0.7 to 0.8 cm in thickness. They were poorly demarcated from the medullae, which were of a purple hue nearest the cortices and pale at the pyramids. There were six yellow stones measuring 2 to 3 mm in diameter within the left pelvis. In addition, there were small yellow granules of sand in the same pelvis. There were three similar stones in the right pelvis. The mucosa of the pelves and calyces were moderately injected. There was no exudate. The ureters and pelves were not dilated. The kidneys showed extensive amyloidosis. There was universal and marked amyloidosis of the glomeruli, interstitial vessels and tubules. The walls of the afferent vessels of the glomeruli were thickened and, for the most part, red and amorphous. Large masses of amyloid were present in the interstitial tissue and capillary walls of the glomerular tufts, resulting in narrowing and obliteration of the capillaries. The basement membrane of Bowman's capsule showed hyaline thickening. With few exceptions every artery or arteriole showed thickening of the walls with amyloid (Fig 2). In many vessels the lumen was obliterated. The veins were only occasionally and irregularly involved. There was amyloidosis of the tubules. This was not extensive and appeared for the most part in

the medulla. The amyloid was found in the region of the basement membrane of tubules. The tubules, however, showed striking changes in addition to the presence of amyloid. In many convoluted tubules some cells were swollen, pale and granular, whereas others were vacuolated and distended and appeared lace-like. The cells were often ruptured and the lumen of the tubules was often filled with pink cytoplasmic debris. No fat was demonstrable with sudan IV stain. Other convoluted tubules were widely distended and the epithelium was flattened. No mitotic figures were seen. A few of the convoluted tubules contained polymorphonuclear leukocytes and others contained masses of cellular debris. No hyaline casts were found. The interstitial tissue was congested. A few small foci of lymphocytes were present.

In the pancreas amyloid was found in the walls of the arterioles of the interstitial tissue. Arterioles of an occasional islet also contained amyloid. The islet and acinar tissue was unchanged.

The pituitary body was of normal size. Sections of the anterior lobe and pars nervosa showed amyloid within the walls of arterioles and in the walls of some veins. There was no apparent change in the cells of the anterior lobe.

The combined weight of the adrenal glands was 30 gm. The left cortex was of normal thickness and of a pale yellow color; the right was thin, shell-like and pale yellow. Both medullae were brown. The two adrenal glands were similar histologically. With lowest power the glands appeared to be almost totally replaced by homogenous, red-staining amyloid with the exception of a very narrow zone just beneath the capsule and the innermost cells of the reticularis and the medulla. The outermost cells of the zona glomerulosa were distinct and free of amyloid and many contained fine vacuoles. These stained faintly with sudan IV. The remainder of the cortex except for a few clusters of cells of the zona reticularis contained considerable amyloid (Fig. 3). For the most part the cells and vessels were completely replaced by masses of amyloid. These were scattered short columns of cells where the cytoplasm blended with adjacent amyloid. Short double rows of cells occasionally separated and forming a tubule-like structure were found surrounded on all sides with amyloid. The cells of the medulla were relatively unaffected although the vessels contained amyloid in their walls. Formalin fixed frozen sections when examined with polarized light after warming and slight trauma showed only a rare doubly refractile body (cholesterol esters). Crushed cortex showed practically no refractile cholesterol esters. Little fat was demonstrable with sudan IV and when found appeared as small droplets within the cytoplasm of the narrow zone of unaffected zona glomerulosa lying beneath the capsule.

This patient with thermal burns developed in the twelfth month a syndrome characterized by profound and progressive weakness, decreased tolerance to barbiturates and general anesthesia, a low temperature, a low blood pressure, a rapid thready pulse, cold clammy extremities, convulsions and coma.

The diagnosis of Addison's disease in crisis was first made on clinical examination alone and was confirmed by the results of laboratory examination, which showed a marked lowering of the serum sodium, chloride and carbon dioxide combining power and an elevation of the nonprotein nitrogen. The diagnosis was further confirmed by the response to the hormonal and salt treatment, after which there was an immediate improvement in the clinical condition of the patient and a gradual return to normal of the sodium, chloride and carbon dioxide combining power and a fall in the nonprotein nitrogen.

Two weeks after specific treatment had been omitted the condition of the patient became worse, with dyspnea, weakness and a fall in the blood

pressure as the principal symptoms, and in spite of intensive hormonal treatment the patient died within twenty-four hours. Post-mortem examination disclosed generalized amyloidosis, with particular involvement of the adrenal glands and kidneys.

The abnormalities of the urine and the elevated nonprotein nitrogen can be explained by the extensive amyloidosis of the kidneys. It is also probable that renal failure contributed to the abnormal electrolyte pattern seen in the blood. The results of

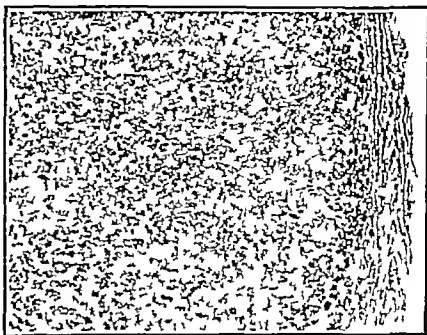

FIGURE 3 Photomicrograph of Adrenal Gland, Showing Marked Deposition of Amyloid in the Cortex Chiefly in the Zona Fasciculata

these electrolyte studies strongly suggest the retention of fixed acids in the blood. Renal failure, in certain cases, closely simulates Addison's disease.⁴

The insulin sensitivity and the decreased glucose tolerance observed on the first day were probably related to the transient disturbance of carbohydrate metabolism often seen following severe burns and other types of stress.⁵ This is borne out by the fact that after the initial period of stress had subsided, the sensitivity to insulin and the glucose tolerance were normal. The sodium and chloride levels and the carbon dioxide combining power were normal on entry.

It is not possible to state categorically the etiology of amyloidosis in this case, which is the only one in which amyloidosis was observed in a series of 60 patients with burns examined at autopsy, many of whom lived several months but none over six months. In addition, a patient with extensive deep burns is still living, with the burns unhealed, after two years who to date shows no evidence of amyloidosis as judged by the Congo-red test. (This patient was discharged well on July 1, 1947, after three years in the hospital.)

It is probable that long-standing infection of the wounds was the chief etiologic factor. Several cultures revealed a hemolytic *Staph aureus* as the predominating organism, alpha-hemolytic streptococci, diphtheroids and *Pr vulgaris* also being present.

in a majority of the cultures. It has been demonstrated that healing and skin grafting of extensive deep burns proceed more rapidly under conditions of adequate nutrition and that, in the presence of malnutrition, local exudation and presumably local infection of the granulating areas are increased.⁶ This patient suffered from long periods of malnutrition during the course of her illness owing to the fact that it was possible to feed her adequately only when special nurses were available. At other times the amount of nursing care available was insufficient, largely because of the universal wartime shortage of nurses. The importance of special nursing care in inducing burned patients to take adequate diets and supplements has previously been emphasized.⁷

On the other hand, it is possible that the intermittent high-protein intake, consisting chiefly of milk, milk powder and Amigen, was a contributing etiologic factor, since feeding of cheese had been reported to cause amyloidosis in animal experiments.^{8,9} At present, however, from the practical point of view, this possibility should be disregarded because of the marked importance of maintaining patients with extensive deep burns in good nutrition and the practical difficulty of administering sufficient

protein unless milk and derivatives of milk protein are freely used.

SUMMARY

A case of Addison's disease associated with amyloidosis of the adrenal glands that was part of a generalized amyloidosis following thermal burns is described. The Addisonian syndrome made its appearance a year after the initial injury.

MEDICAL PROGRESS

WAR WOUNDS OF THE ABDOMEN

CLAUDE E. WELCH, M.D.*

BOSTON

A COMPLETE treatise covering all aspects of abdominal wounds observed in the United States Armed Forces in World War II probably will not be available for several years. On the other hand, many excellent articles on various phases of the problem have recently appeared. It seems worthwhile to collect and summarize the outstanding contributions that have been published before memories grow dim and interest flags. Obviously, no attempt can be made to include all papers. Nor can extensive considerations of tactical situations, closely related though they are to the care of the wounded, be included here.

The recent surgical care of the wounded differed radically from that in previous wars.[†] The extent of this change may be gauged by a brief summary of the therapy of abdominal wounds in the past. Interestingly enough, even in the early part of World War I all such wounds were treated con-

servatively just as they had been formerly.¹ Then a new era in surgery was inaugurated. It became apparent that nearly all patients with such wounds were sure to die unless operated on. Many of the wounded in World War I, however, were not admitted to a hospital for therapy as shown by the fact that of patients admitted to the hospitals only 11 per 1000 suffered from abdominal wounds. In the Fifth Army in the recent war 35 men per 1000 entered with abdominal wounds.²

It gradually became apparent that the time lag from wounding to surgical treatment must be reduced to the shortest possible interval if these patients were to survive. This was achieved in the Spanish War by the "three point forward system," described by Jolly,³ who stated that abdominal wounds represent the best example of the type of case in which the time lag is supremely important for the saving of life. To achieve a reduction in the time lag, the casualty clearing station was divided into a casualty classification post, a hospital for the most urgent cases, including abdominal injuries,

*Instructor in surgery, Harvard Medical School, associate visiting surgeon, Massachusetts General Hospital, formerly, lieutenant colonel, MC A U S.
†Dr. Edward D. Churchill kindly contributed suggestions and data on the subject of initial surgery of battle wounds.

Find a second hospital for the less urgent. All three were separated, however, by ambulance transportation involving some delay between the triage center and the first hospital.

The British in the Libyan Campaign in World War I gradually evolved a method that was somewhat similar. The wounded were evacuated from the field dressing station by ambulance. As successive installations equipped for surgery were reached in the chain of evacuation, the most urgent cases were taken from the ambulances and retained for treatment. The selection was often cursory, however, and since the distance between the stations often required many hours of travel, many patients had to be evacuated too far.

The method employed by the United States Army was planned during the North African campaign and was first employed in the invasion of Sicily. Thereafter, it was used throughout the war in the Mediterranean and European theaters. This procedure of triage undoubtedly contributed more to the saving of lives of the patients with abdominal wounds than any other single factor. The method was essentially as follows:

All casualties from the divisional area were collected at the clearing station, immediately adjacent to which a section of a field hospital was established. This institution was staffed by attached surgical teams composed of skillful surgeons, anesthetists, nurses and enlisted personnel with adequate equipment. Thus, even though the team was operating in the most unpleasant and often dangerous situations, the best care could be furnished the soldier at the time when operation was essential. Furthermore, resuscitation and surgery were amalgamated rather than dissociated as they had been in the past. Less urgent cases were sent immediately from the clearing stations to evacuation hospitals by ambulance. Likewise, patients from field hospitals were transferred to evacuation hospitals after initial surgery had been performed and convalescence well established. The dangers of early evacuation of these casualties had previously been shown by the British in the Middle East. Consequently, the field hospital was equipped to care for its patients in the early postoperative period.

Thus, during this war a new mode of treatment of abdominal casualties, based on the following considerations, evolved: the concept that abdominal injuries produce patients who are essentially non-transportable, surgery and early convalescence being transferred to the rear boundary of the division rather than the wounded being sent to the surgeon in the rear, the principle that resuscitation of patients with abdominal wounds must be rapid and effective, with the result that blood and plasma had to be instantly available in large amounts and surgery became an integral part in the process of resuscitation, the consideration that surgery must be radical and the benefits denied to none, and the concept

that proper anesthesia is of the utmost importance if the patient is to survive — the anesthetist is no longer an "etherizer" but must be prepared to cope with all hazards of all types of anesthetics and to play an important part in the resuscitation of the wounded, as well as in the prevention of post-operative pulmonary complications.

New technical details that are of major importance in the management of abdominal wounds also

evolved in World War II. The most important are as follows:

The exteriorization of wounds of the colon. Although this maneuver was employed in large ragged wounds of the colon in World War I, its value was not established until World War II. Kirk⁵ described it as one of the important surgical advances in this war.

The evolution of an effective method of treatment of rectal wounds. The "retropentoneal syndrome," with death from extensive infection, was practically eliminated by wide local drainage and colectomy.

The thoracic approach for thoracoabdominal wounds. Dependent on advances in anesthesia, this technic has been almost wholly the product of World War II.

The elimination of enterostomy as a method of treatment of wounds of the small intestine.

The advances are reflected in various statistics that have appeared. Thus, the over-all mortality of patients with abdominal wounds admitted to American Expeditionary Force hospitals in World War I was 66.8 per cent.⁶ The mortality of 381 such cases treated in the British Eighth Army during a three-month period in 1942 was 42.5 per cent.⁷ In 2918 abdominal cases that had visceral wounds operated on by the Second Auxiliary Surgical Group in World War II the mortality was 25.5 per cent.⁸ These figures do not adequately measure the actual improvement, for in World War I, only less severe wounds were operated on and fewer patients reached

the hospital. Thus, the mortality rate of the Second Auxiliary Surgical Group patients of a character comparable with those of World War I was about 13 per cent. On the other hand, the over-all mortality for all the armed forces will not be so low as that of the Second Auxiliary Surgical Group.

A comparison of the over-all mortality of the wounds of the various viscera in the American Expeditionary Force¹ in World War I and in the British Eighth Army (Libyan Campaign)⁷ and the Second Auxiliary Surgical Group² in World War II is presented in Table 1. It will be noted that, because of the high incidence of wounds of multiple viscera, the over-all patient mortality is much less than that when the viscera are considered separately.

Several methods have been proposed to estimate the prognosis of the wounded. The most important are the time lag, the depth of shock on arrival in the field hospital and the multiplicity factor. These procedures require further consideration.

The time lag has been investigated by many surgeons, in an attempt to prove the obvious truth that delay in treatment increases the death rate. The variability of war wounds, however, introduces factors that make most such studies worthless. Thus, Brott and Childs² found that, if all cases are considered, "the mortality of any unselected groups of abdominal cases at any selected time interval from wounding to surgery is approximately constant." Ogilvie⁷ even observed that an increased time lag works both ways, but chiefly toward a lower operative death rate and that delay causes peritonitis but also eliminates the worst cases. Consequently, Brott and Childs studied the mortality when the two variables—the time lag and the number of abdominal organs involved—were separated. These figures show clearly that the death rate rises with delayed treatment. Giddings and McDaniel,² studying a series of 355 cases in which the small bowel was the only viscus injured, found the mortality to be 7 per cent if the operation was done within eight hours. The mortality rose to 14 per cent in twelve hours, 22 per cent in twenty-four hours and 30 per cent in forty-eight hours.

The depth of shock is difficult to estimate. Among the important considerations are the level of the blood pressure, the rapidity of the pulse, the pulse pressure, the state of the peripheral circulation as evidenced by cold, pale or cyanotic extremities and signs of cerebral anoxia. Of these features the most reliable, according to Towery,² are the trends of the blood pressure and pulse as resuscitative therapy is carried out. Beecher⁸ noted that the pulse rate and the amount of sweating are of no value in estimating the depth of shock, on the other hand, the fullness of the pulse and the blood pressure level are of great importance. Since the blood pressure is the most reliable objective criterion of these features, the degree of shock has usually been measured by the level of the systolic pressure.

Towery and Welch² grouped their patients of Second Auxiliary Surgical Group in four categories. The degree of shock was said to be profound if systolic blood pressure on admission was 40 or below, severe from 41 to 70, moderate from 71 to 100 and incipient or no shock from 101 to 140. The mortality in these four groups was respectively 66.4 per cent, 50.4 per cent, 38.0 per cent and 18.1 per cent. These data show clearly that the prognosis may be estimated with some accuracy at the time the patient arrives in the field hospital.

The "multiplicity factor" has been shown to be of extreme importance in the determination of prognosis. This factor, as defined by Wolff, Chaffin and Giddings,² refers solely to the number of abdominal organs injured in a given case as determined at operation. In 2918 cases of abdominal wounds the mortality was 12 per cent if one organ was involved, 27 per cent with two, 46 per cent with three, 60 per cent with four and 88 per cent with five organs involved.

The nature of wounds of the abdomen caused by high-velocity shells has been investigated by Puckett, McElroy and Harvey.⁹ Their studies show that the abdomen expands with the penetration of a high-velocity missile. This expansion persists for 1 or 2 milliseconds, and is followed by a constriction that lasts for 4 or 5 milliseconds and is succeeded by a second bulging of the abdominal walls of greater duration but less intensity. Coincident with the initial abdominal expansion there is a large temporary cavity within the abdomen. Internal damage to the viscera is far out of proportion to the wounds of exit and entrance. The general effect is that of an explosion within the abdomen.

The care of the wounded may be classified according to Churchill,¹⁰ into initial, reparative and reconstructive phases. In terms of Army installations of World War II, this means essentially the care furnished first by the field and evacuation hospitals, secondly by the overseas general hospitals and finally by the general hospitals in the Zone of the Interior. Further discussion of abdominal wounds is divided into these three categories.

INITIAL SURGERY

Abdominal casualties must be evacuated rapidly as possible to a surgical unit prepared to handle them. Only primary measures of resuscitation, such as plasma administration and the tourniquet control of hemorrhage from accompanying wounds of the extremities, are employed before the patient reaches a surgical installation.

As soon as the patient arrives in the field hospital, resuscitation is begun, his clothes are removed, his wounds are inspected, and he is placed on a gurney. Thereafter, a rapid estimate of his general condition is made, x-ray films are taken, the stomach is lavaged, the urine is examined, pain is alleviated.

chemotherapy is begun, and surgery is instituted. Several of these measures require special consideration.

Resuscitation in abdominal cases involves primarily the administration of blood.¹¹ Plasma is administered while cross-matching is carried out. Thereafter, if the patient is in shock, 1000 cc of blood should be given in fifteen to twenty minutes and continued at a slower rate. The average abdominal case requires 1500 to 2000 cc.

The maximum time devoted to preparation of patients should be one and a half to two hours. If at that time there has been no response to treatment the usual causes of persistent shock must be considered. They are, according to Berry,¹² continuing hemorrhage, massive peritoneal contamination, pelvic cellulitis or clostridial myositis, a large evisceration, blast injury of the lungs, heart, abdomen or brain or other severe wounds.

Physical examination is directed especially toward a determination of the course of the missiles. All evidence points to the fact that they pursue straight courses through the abdomen. Any penetrating wound of the chest, back or thigh may represent a possible abdominal penetration. According to Stewart,¹³ the most important errors in the pre-operative physical examination are failure to examine the rectum and omission of an examination of the peripheral nerves. If the possibility of a rectal wound exists and no blood is found on the examining finger, a proctoscopy must be done.

Auscultation of the abdomen is of value. Jarvis¹⁴ found peristalsis to be uniformly absent with intraperitoneal perforation of a hollow viscus. On the other hand, absence of peristalsis is not diagnostic of perforation. Blackburn and Rob¹⁵ observed peristalsis in the presence of lesions of the hollow viscera in only 5 of 89 cases, whereas in the absence of hollow visceral lesions, peristalsis was present in 64 cases and absent in only 1. Estcourt¹⁶ noted active peristalsis in several patients who at operation were found to have perforation of the colon.

The primary purpose of x-ray examination is to determine the location of retained fragments and thereby to visualize the path the missile has taken.

The stomach tube, preferably one of large caliber, is passed, and the stomach emptied. It is a fortunate event when vomiting is induced by this maneuver.¹⁷ Thereafter, a Levin tube is introduced and maintained during and after operation. Beech and Wolff¹⁷ demonstrated that, with few exceptions, this procedure should be an integral part of the preoperative resuscitative program, regardless of the site of the wound.

If the patient cannot void, a catheter must be passed and the urine examined. If bloody urine is obtained it is better to avoid irrigation of the catheter until the abdomen is opened (Michels¹⁸).

Pain is more frequent after abdominal wounds than any other type.¹⁸ Consequently, many patients

have been oversedated and during the progression of resuscitation have developed acute morphinism. Therefore, it is better to administer morphine by the intravenous route and in comparatively small doses.

Chemotherapy, which is instituted as soon as the patient arrives, usually consists of the intramuscular administration of 25,000 units of penicillin although, when available, up to 100,000 units has been given intravenously. The whole problem of chemotherapy is considered below.

When the patient is ready for surgery or when surgery becomes mandatory because his condition fails to improve, the anesthetic is begun. This should preferably be ether oxygen administered by a closed system through an intratracheal tube. To avoid the deeper levels of anesthesia, local or regional nerve blocks may be added. This is especially true in the upper abdomen, where the intercostal nerves may be blocked. Spinal anesthesia is contraindicated because of the deleterious effect on blood pressure. Pentothal sodium should not be employed as the primary anesthetic agent if there is any likelihood of abdominal penetration, since a long operation with adequate relaxation may be necessary.

The incision should give adequate exposure of the wounded section of the abdomen and should permit secure closure. Thus, if a colostomy may be necessary, the primary incision should be placed well away from the projected site of the stoma. Vertical paramedian incisions are usually preferable. In the upper abdomen, transverse or subcostal incisions may be used. Incisions through the wounds of entrance or exit, and transverse lower abdominal incisions should be avoided.

Ogilvie⁷ states that "in the abdominal surgery of warfare technique may be summed up as a simple plan, a purposeful over-haul, and a rapid repair." Usually, on opening of the peritoneal cavity, blood, fecal matter or a mixture of both is encountered. The cavity is emptied of its fluid contents as rapidly as possible. If hemorrhage continues, usually the spleen, liver or large intra-abdominal veins have been wounded. Primarily, bleeding is controlled. Wounds of the abdominal wall should be carefully inspected, since they may furnish the site of the hemorrhage. Thereafter, the source of fecal contamination is determined. The colon is examined first, and any wound carefully walled off. The small bowel and stomach are observed in that order, and, finally the other viscera. When the entire damage has been ascertained, the various wounds are repaired.

Visceral Wounds

The incidence of involvement by organs in 2918 patients with visceral wounds received by the Second Auxiliary Surgical Group was as follows: stomach, 132 per cent, duodenum, 37 per cent,

jejunum and ileum, 37.0 per cent, colon and intraperitoneal rectum, 35.0 per cent, extraperitoneal rectum, 4.9 per cent, liver, 26.7 per cent, gall bladder and bile duct, 1.7 per cent, spleen, 10.8 per cent, kidney, 13.4 per cent, ureter, 0.8 per cent; urinary bladder, 4.9 per cent, pancreas, 1.9 per cent, and major abdominal vascular injury, 2.4 per cent.² The over-all mortality rate in this series was 25.5 per cent, varying from 26.6 per cent in winter to 19.7 per cent in summer. It was found that children and the aged wounded civilians withstood operative procedures poorly. Of the deaths, 48 per cent occurred on the day of operation, and 62 per cent within seventy-two hours. The causes of death were listed as shock (62.4 per cent), pulmonary complications (12.8 per cent), peritonitis (12.0 per cent), anuria (4.6 per cent), anaerobic infection (1.6 per cent), miscellaneous (4.0 per cent) and unknown (2.5 per cent).

Wounds of the following viscera are briefly considered.

Stomach Wounds of the stomach may be suspected preoperatively if blood has been vomited or aspirated through the nasal tube. The course of the missile in the series of the Second Auxiliary Surgical Group was thoracoabdominal in 47 per cent of cases, and abdominal alone in 53 per cent. Bolman and Caul¹⁹ point out that the perforation may be entirely intrapleural, so that abdominal signs are entirely absent. It is clear that unless every possible penetrating wound of the diaphragm is explored, many of these wounds will be overlooked. The perforation of the stomach is often difficult to locate, especially if the abdominal approach is necessary and the laceration is high on the greater curvature. It is well to remember, as in all other wounds of the gastrointestinal tract, that unless the foreign body is found within the lumen of the viscus, there must be an even number of perforations, barring tangential lacerations.

Closure of the stomach should be by a careful two-layer suture. Purse-string sutures should be avoided, since secondary hemorrhage is more frequent from the stomach — because of its extraordinary vascularity — than from any other part of the gastrointestinal tract. No data can be offered concerning the merit of absorbable or nonabsorbable sutures in any part of the gastrointestinal tract. Many surgeons had more confidence in an outer layer of cotton or silk because of the established peritonitis present in most of the cases. Other surgeons used catgut throughout.

Duodenum In the great majority of wounds of the duodenum, the wound of entrance is in the right upper quadrant or in the back, posterior to the duodenum. The mortality is high because other viscera are frequently damaged. Accurate exposure of the retroperitoneal duodenum requires mobilization of the hepatic flexure of the right colon and section of the lateral attachments of the duo-

denum. In this manner the entire organ may be inspected. Repair is effected either by a two-layer closure or by resection and anastomosis.

If the patient survives the first few postoperative days, a fistula will form unless the closure has been satisfactory. In 20 cases in which transections were observed in the Second Auxiliary Surgical Group, only 6 patients lived through the sixth postoperative day, and fistulas developed in 2.

Jejunum and Ileum The small intestine is wounded oftener than any other abdominal viscus. Perforations are usually multiple and, because the ileum is longer than the jejunum, are more frequent in the former. It is essential to inspect all wounds of the intestine before repair, since if a resection is necessary other wounds may be included in the excised segment. Repair is either by suture or by resection and anastomosis. A two-layer end-to-end anastomosis is usually the procedure of choice, if resection is to be done, since it can be made more rapidly than a side-to-side anastomosis. It must be made with care to avoid late obstruction at the anastomotic line.

The individual surgeon must decide which procedure is to be employed. The British have recommended resection only as a matter of last resort. It was used much more frequently in United States Army hospitals. The essentials are first that all traumatized areas must be repaired and secondly, that the remaining blood supply must be adequate. Thus, any segment of intestine from which the mesentery has been detached for 5 cm or more should be resected because gangrene and perforation will occur later if it is left in situ. One resection can frequently dispose of several lacerations and severely traumatized bowel, in my opinion, this is more satisfactory than leaving areas of questionable viability that may perforate at a later time. Severe damage to the mesentery will also require surgery. It is to be expected that the mortality after resection will be higher than that after suture, because more serious injuries are included. Thus, Giddings and McDaniel² found in 1117 cases that the mortality following suture was 23.3 per cent and that after resection, 37.3 per cent.

Under no circumstances is an enterostomy desirable, except as noted below in wounds of the cecum. The depletion from rapid loss of secretions of the upper intestine is formidable. Fortunately, recourse to enterostomy was rare in World War II.

An interesting postoperative complication was reported by Hawkes and Spencer.²⁰ Following a thoracoabdominal wound with perforation of the upper small intestine and colon, there was massive bleeding from the colostomy. A total of thirty-five transfusions was employed. Twenty-two days after the injury, exploration revealed hemorrhage from an artery at the site of the closure in the jejunum. Resection was followed by recovery.

Colon The treatment of wounds of the colon has provoked more discussions than that of injuries to any other viscus. From a mortality of about 60 per cent in World War I, the death rate has been nearly halved, particularly because of the widespread adoption of the principle of exteriorization. The method, however, varies depending on the section of colon that is wounded.

It is important, in a discussion of wounds of the colon, to differentiate clearly three types of surgical procedures. In the first group a perforation of the bowel is discovered, the loop is exteriorized, and the "colostomy" has already been made by the missile. In a second group, there is extensive soft-tissue damage to the buttocks or a wound of the low sigmoid, but a careful suture of the perforation of the colon is possible, in these cases the sigmoid is exteriorized, and a small incision is made for temporary decompression that may be converted into a defunctioning colostomy by complete transection should it be needed. In the third group extensive wounds of the lower bowel, bladder or pelvis require a true colostomy that will entirely defunction the distal segment.

There are certain essential features in any colostomy. It should be placed in a separate incision from that employed for the laparotomy. Usually, a small muscle-splitting incision can be made. Wounds of entrance or exit should be avoided unless they are small, because of the increased chance of sepsis or breakdown. Adequate mobilization is most significant. The forward surgeon should remember that postoperative abdominal distention will shorten the colostomy and invite retraction into the abdominal wall. Most of the complications referable to colostomies observed in the overseas general hospitals could have been avoided if a proper site had been chosen for the colostomy, and the bowel widely mobilized.²¹

Colostomies are either of the loop or of the spur type. Acrimonious discussion was often heard from the partisans of both types in the overseas hospitals. Later, some surgeons working in the general hospitals of the Zone of the Interior advised complete division of both limbs of all colostomies to avoid any spill-over of feces from the upper to the lower segment. To the impartial observer, it seems that all these procedures have their indications.

The whole problem has been ably discussed by Mason,²² who divides these wounds into the following groups: perforation of the antimesenteric portion up to half the diameter of the segment, which is best treated by a simple, no-spur, loop colostomy; perforations of the mesenteric border and of the antimesenteric border larger than half the diameter, which should be treated by a double-barrel spur colostomy; severely torn segments and complete transections, which also require a double-barrel spur colostomy; injuries to the mesentery producing nonviable segments, which are treated in the same

way, a sixth group, which includes the first five groups but in the injury to the rectosigmoid just above the peritoneal floor, in which repair must be effected and a loop colostomy done proximal to the injury, a seventh group, which includes the first five groups occurring in the rectum between the pelvic peritoneum and anus and in which Mason advises a loop colostomy, and injuries of the right portion of the colon necessitating right colectomy or cecectomy, which are probably best treated by a spur ileocolostomy. In addition, Mason states that areas of questionable viability may be exteriorized. Any perforation in an exteriorized segment may be closed, occasionally, the suture will hold.

Disagreement with the above conclusions will occur chiefly in the seventh and eighth groups. The rectal wounds are considered below, but it is necessary to discuss injuries of the right portion of the colon more fully here.

Wounds of the antimesenteric margin of the ascending colon may be converted into tube cecostomies. Small perforations without contusion of the bowel may be closed primarily by experienced surgeons. A large rubber tube is employed and is withdrawn in four or five days. If there is a small posterior wound of the cecum as well, it may be closed by suture, it is always important to mobilize the whole ascending colon to disclose such perforations.

A more difficult problem arises when there has been extensive damage to the ileocecal area and this whole segment must be resected. There are several ways of handling the bowel. Primary ileocolic anastomosis has occasionally given brilliant results, but is not recommended as a routine procedure, since the peritonitis produced by wounds of the ascending colon is the most virulent from all colonic injuries. A spur-type ileocolostomy may be done, the stoma being brought out in a separate incision. The profuse ileal drainage will be difficult to handle, serious problems in wound healing arise, and even deficiency states may appear quickly. Many surgeons followed this technique to the end of the war, holding the patients in the forward hospital for early (three or four days) crushing of the spur. This difficulty may be obviated by a side-to-side ileocolostomy, either the distal ileum or the proximal colon, or both, being brought out for decompression. A final suggestion is an ileocolostomy with wide separation of the two limbs.

The experience of the Second Auxiliary Surgical Group is of interest in this regard. The conclusions of Chunn and Hauver²³ were as follows:

Wounds of the ascending colon presented a particularly difficult problem when it was necessary to resect the entire right colon and terminal ileum. Early in the war the most popular procedure was the resection and double-barrel ileocolostomy. This procedure was not satisfactory and carried a mortality rate of 64.7 per cent. Later on, resection and ileocolostomy anastomosis and either double mucous fistulae or single mucous fistula were advocated.

and was done with some improvement in the mortality rate. However, this mortality rate remained high at 51.7 per cent. Two patients with resection of a portion of the ascending colon had the proximal and distal ends exteriorized and both patients died.

If a loop colostomy is to be made, the loop may be supported by a glass or rubber tube. If a spur colostomy is made, the spur should be made 15 cm long, and it should project 5 cm above the skin. The spur should be formed by two catgut sutures along the antimesenteric margin. The bowel should be opened on the operating table if the perforation is distal to it. In other cases it may be advisable to leave the clamp on for twenty-four hours until the wound is well sealed off.

Rectum. Wounds of the rectum are characterized by difficulty of diagnosis, inaccessibility, frequent damage to other structures, and the hazard of retroperitoneal infection. Laufman²³ notes that the missile may enter anywhere from the costal margin to the lower thigh. Only 6 per cent of patients with buttock wounds in his series had rectal perforations. The patient usually escapes injury to the rectum unless the missile crosses or is lodged near the midline. Patients with unsuspected and untreated rectal wounds are likely to die of profound toxemia.

When a rectal wound is present or suspected, the posterior wound should be débrided before the laparotomy is done, unless active intra-abdominal hemorrhage demands initial laparotomy. This will require adequate exposure of the tract of the missile, as well as exposure of the rectum through an anococcygeal incision that must be deepened through the fascia propria of the rectum. The coccyx will frequently need to be moved to secure wide drainage. If so, because of the possibility of osteomyelitis of the lower sacrum, as noted by Colcock,²⁴ the bone should be cleanly removed and the sacrococcygeal cartilage excised. The rectal wound is exposed. Closure is advocated by Croce, Johnson and Wiper²⁵ and Mason,²² even though the chances of failure are high. The wound is packed lightly.

Laparotomy is then performed. If the rectal wound is small and uncomplicated a sigmoid colostomy with separation of limbs is wise. If there is extensive damage to bony pelvis and bladder, the colostomy should be made in the transverse colon.

A rectal wound is often first diagnosed at laparotomy. A retroperitoneal hematoma arising from the pelvis usually indicates damage to the rectum, and a colostomy should be performed accordingly.

Morgan²⁶ lists some of the complications that have been observed — namely, osteomyelitis, meningitis following removal of a shell fragment near the sacral canal, diphtheritic infection and secondary hemorrhage.

(To be concluded)

EDITH E. PARRIS, *Assistant Editor*

CASE 33311

PRESENTATION OF CASE

A twenty-four-year-old man was admitted to the hospital because of pain in the back.

Two weeks prior to admission the patient noted a steady dull aching pain in the right flank, lasting about five or six hours and then subsiding. Four days later it recurred in the left flank, and subsequently he was never free from pain in either the right or left flank. The pain radiated to the front of the abdomen, was sometimes made worse by deep breathing, caused anorexia and at times prevented sleep. He had taken fluids without vomiting. He had noted an evening rise in temperature since the onset of the pain. On the day of admission he hiccuped continuously.

Since the age of eight the patient had noted increasing muscular weakness. Early there was a contracture of the toes, so that walking was possible only on the toes. Because of increasing weakness of the legs walking had been impossible for the past eight years, and by the time of admission the trunk and upper extremities were so weak that the patient could not lift his arms to shoulder level and could not arise in bed without aid. One year before entry he had suffered from palpitation, breathlessness and swelling of the legs. His physician told him that he had high blood pressure and gave him digitalis, which afforded considerable relief.

His parents were living and well but one brother out of five siblings and a maternal cousin suffered from similar muscular weakness.

The patient appeared too acutely ill to permit extensive examination. He was obese, and the muscles were generally weak, although they appeared and felt hypertrophied, especially the calf muscles and biceps. The lower extremities were cold, livid and pulseless. The fundi were poorly visualized but revealed narrowed arterioles. The throat was slightly injected. The chest was clear. A forceful apex impulse was felt 3 cm. beyond the midclavicular line, and a Grade I systolic murmur was audible at the apex. The pulmonary second sound was considerably louder than the aortic. The abdomen was distended and tympanitic, with diminished peristalsis. There was tenderness in the right costo-

vertebral angle and right flank and to a less extent in the left costovertebral angle. There was extreme weakness of all extremities, with equinus deformities of the feet and hypertrophy of the calf tissues.

The white-cell count was 15,800, with 92 per cent neutrophils, the red cell count was 5,100,000, with 15 gm. of hemoglobin. The urine on two occasions gave a +++ test for albumin, and the sediment showed occasional hyaline and granular casts and, on one examination, 30 to 40 white cells and 2 to 3 red cells per high-power field. X-ray films revealed enlargement of the heart, particularly in the region of the left ventricle. The cardiac apex lay within a fingerbreadth of the chest wall. There was questionable notching of the ribs. The aorta could not be traced. The lungs were clear. There was an area of translucency between double contours of the right leaf of the diaphragm.

The temperature rose from normal on admission to 103°F. in the afternoon and fell to normal again by the following morning. The pulse was around 120, and the respirations about 20. The blood pressure was 110 systolic, undetermined diastolic.

Hiccups continued the day after admission, and the patient complained of some shortness of breath. The nonprotein nitrogen was 54 mg. per 100 cc. Later that day he was found to be breathing in Cheyne-Stokes rhythm, the neck veins were distended, and the pulse was 120, with an audible gallop. He was cold and sweaty, and the blood pressure was not obtainable. The chest was clear to percussion and auscultation. Later in the morning he improved, the blood pressure was 90 systolic, 70 diastolic, and the pulse was still 120, and the breathing was regular. An electrocardiogram was not remarkable, except for evidence of some degree of bundle-branch block. By evening the respiratory difficulty had again developed, without evidence of fluid in the chest. He expired at 1:00 the following morning, forty-eight hours after admission.

DIFFERENTIAL DIAGNOSIS

DR. MARIAN ROPES. To me this picture is extremely confusing. Many systems are involved, and it is difficult to find the interrelation between the diseases. The predominant involvement is in the neuromuscular, cardiovascular and renal systems, with possible or probable gastrointestinal-tract involvement. The neuromuscular involvement was of sixteen years' duration and consisted of progressive muscular weakness. There are various causes of such a condition that one must think of. Myasthenia gravis is the first, for which I find little evidence. There is no evidence for dermatomyositis. I think that the likeliest explanation for such a steady progressive muscular weakness with some disproportion in the size of muscles is myopathy—muscular dystrophy. If this is the cause of the muscle disease, there is no evidence that it is related to the terminal illness, which began two weeks before death. It

would be intriguing to try to link them together, but the only possible way that I can is by some involvement of the vascular system, presumably an anomaly of some kind. On admission the legs were cold and pulsations could not be felt. There was also questionable notching of the ribs. It seems probable to me that the majority of the changes in the legs were of acute onset and related to the terminal illness. Whether or not he had any alteration of blood supply to the lower extremities before the last two weeks is difficult to say. Perhaps at this time the x-ray films would help us out, especially in regard to the questionable notching.

DR STANLEY M. WYMAN: The films could not be found for demonstration here, but I remember that we argued about them at some length. It was the majority opinion that they were not true notches, since they all occurred at the same area in the rib.

DR ROPES: That is disturbing because there are two differential points that I had hoped the x-ray films could help us with. One was the question of notching. If notching was present, coarctation should be seriously considered.

The second question is whether or not the area of translucency was definite enough to conclude that there was air under the diaphragm. Apparently we are not going to have the opportunity to look at the films to see if it was impressive enough to include rupture of a viscus as one of the possibilities.

To return to my attempt to see if in any way the neuromuscular disease can be linked to the terminal illness, vascular anomaly has to be considered. Coarctation alone would not, to my mind, explain the weakness involving the upper extremities. Progressive weakness and atrophy of all extremities can occur with hypoplasia of the aorta. This may be found with a large or small heart, and it is usually associated with accentuation of the pulmonic second sound, which was present here. The course of such a condition, however, is slowly progressive congestive failure. I see no evidence of such progressive congestive failure in this case. I doubt that hypoplasia of the aorta could explain all this picture and therefore it is not a way of linking the neuromuscular disease to the terminal disease.

To turn to the final illness of two weeks' duration, I find three possibilities that have to be seriously considered. The first is rupture of a viscus, which I have mentioned. The seriousness with which we consider this depends to some extent on whether or not there was air under the diaphragm. If rupture occurred I doubt that it happened at the time of onset of symptoms two weeks before admission. It is much likelier that infarction occurred at that time and then eventually, rupture. I should expect, however, more evidence of peritoneal irritation at some time during the course than is apparent here. The terminal episode would presumably have to be explained by some secondary event, such as pulmonary embolism.

Another group of events, which I considered as one of the possible explanations, is embolism, pulmonary or renal, or both. There is little definite evidence for pulmonary embolism anywhere in the story. The increased pulmonary tension is suggestive evidence, but surely not more than that. The location of the pain — in the flanks and abdomen — is unusual for that associated with pulmonary emboli. Again if one considered that pulmonary emboli occurred in this patient and were the cause of the terminal episode, one would have to introduce other factors to explain certain findings, such as the renal disease. That could have been caused by pre-existing renal disease or by emboli to the kidneys with infarction. There is absolutely nothing in the history to indicate the former unless one considers the slight suggestion of arterial narrowing as suggestive. The pain is surely consistent with the latter diagnosis, but the location is utterly consistent. In regard to the source of such emboli in the systemic circulation, I find it necessary to introduce the possibility of infection, either on an abnormal aortic valve, for which there is little evidence, or coarctation, if such exists. The laboratory evidence in this case is of little help in differentiation. We have evidence of leukocytosis, with a polymorphonuclear reaction and fever. If one considered renal emboli as the initial episode one would have to introduce something else to explain the cause of death — such as a pulmonary embolus or disease in the aorta.

The third possibility is a dissecting process in the aorta. If this were present, one would see it in a patient of this age only in the presence of some vascular anomaly. It could occur in a person with coarctation of the aorta, in which case the final dissection and rupture could reach the pericardium and cause pericardial tamponade. In this respect it would be helpful to know that there really had been a sudden cardiac enlargement. That is something we cannot know, however. The final picture, I think, is consistent with bleeding into the pericardium.

In reconsidering the total picture, I find it difficult to differentiate these three groups of possibilities, for which there is little evidence. So far as I am concerned it is a choice between three types of possibilities, no one of which satisfactorily explains all aspects of the picture. I neglected to say that, had dissection occurred from coarctation of the aorta it is conceivable that increased obstruction to flow could have caused decreased blood supply to the legs and kidneys with infarction explaining the renal findings. So if I still must choose between these three groups in the absence of being able to determine which is the likelier, I will place first the uncommon possibility, namely, coarctation of the aorta, with subsequent dissection and rupture. The possibility of superimposed infection cannot be ruled out. I think the best explanation of the

neuromuscular findings is muscular dystrophy, although it is intriguing to attempt to conceive that this whole process was related to generalized vascular disease or possibly to a vascular anomaly.

DR WALTER BAUER How tall was this man? How much did he weigh?

DR TRACY B MALLORY He weighed 210 pounds. He looked like a powerful man, around 6 feet tall.

DR ROPES I was thinking of a small person, I must admit.

DR BAUER How many white-cell counts were done?

DR MALLORY Only one is recorded.

DR BAUER Were there any eosinophils in the smear?

DR MALLORY No.

DR TAYLOR, do you want to give us the impression on the ward?

DR ISAAC TAYLOR I saw the patient in the Emergency Ward. He presented the picture of shock and severe pain in the back, in addition to what appeared to us to be muscular dystrophy.

DR BAUER Where in the back?

DR TAYLOR In the right costovertebral angle radiating around the right flank toward the inguinal region.

At that time he gave a history of having been in congestive failure one year previously, and in response to pointed questioning he said that the doctor had told him that he had high blood pressure. He was placed on digitalis and maintained a normal pressure until shortly before admission. The impression in the Emergency Ward was that he was suffering from congestive failure, which accounted for the low blood pressure in the face of a history of high blood pressure. The x-ray films of the lungs were clear, showing no evidence of congestion.

DR BAUER What were the signs of congestive failure?

DR TAYLOR Cyanosis and respiratory distress. The enlargement of the heart on x-ray examination was quite marked, with a prominent left ventricle.

DR BAUER Did the pain radiate anywhere other than to the anterior abdominal wall? Did it go to the legs?

DR TAYLOR No. It radiated from the right costovertebral angle around the right flank to the inguinal region. It did not go into the testicles or legs.

DR BAUER Were the heart sounds distant or faint? Was there a gallop rhythm?

DR TAYLOR The heart sounds were of good quality. I heard no gallop.

DR MALLORY Dr Ropes, do you care to say anything more?

DR ROPES I think not.

DR BAUER I am tempted to suggest another possibility on the basis of the white-cell count, which was 15,000, with 92 per cent neutrophils, and a temperature of only 101°F. The count seems

out of proportion to the degree of fever. In bizarre cases such as this, these findings should always cause one to entertain the possibility of periarthritis nodosa. I believe that periarthritis nodosa with an aneurysm or two could explain everything this man had. On first reading the case, I wondered about congenital hypoplasia of the vascular system. This man's size and weight are against that diagnosis, however. I take it that he had pseudohypertrophic muscular dystrophy, particularly with the family history. Just to throw in another red herring, I shall say that the diagnosis was periarthritis nodosa, with a few mycotic aneurysms, one of which may have ruptured.

CLINICAL DIAGNOSES

Progressive pseudohypertrophic muscular dystrophy

Coarctation of aorta

Glomerulonephritis?

DR ROPES'S DIAGNOSES

Muscular dystrophy

Coarctation of aorta, with dissection and rupture into pericardium

Renal infarction?

ANATOMICAL DIAGNOSES

Pseudohypertrophic muscular dystrophy

Fibrosis of myocardium

Cardiac hypertrophy and dilatation

Mural thrombi, left ventricle

Infarcts of spleen and kidneys

PATHOLOGICAL DISCUSSION

DR MALLORY Although this was the type of case in which we should have liked to do everything, the post-mortem examination was limited to an abdominal incision. I believe that we have most of the answers, however. The heart was greatly hypertrophied, weighing 600 gm. There was no coarctation of the aorta, but the aorta was extremely small, measuring only 4.5 cm in circumference. The lungs were congested and showed no infarcts. There were no pulmonary emboli. The cause of the flank pain was quite obvious when we looked at the kidneys. The right kidney was totally infarcted, apparently in two stages, since the upper pole was yellow whereas the lower one was grayish red. The right renal artery was completely occluded by a thrombus. The left kidney, which was larger than the right, showed a single large infarct. The left renal artery was patent. The liver showed marked chronic passive congestion, with necrosis of the cells in the central half to two thirds of the lobules. The spleen was enlarged, firm and congested and weighed 400 gm. We believe that there was adequate anatomic evidence for a diagnosis of cardiac failure. Whether the immediate mechanism of death was renal, cardiac or peripheral circulatory failure is impossible to decide on anatomic grounds.

The skeletal muscles showed almost complete replacement with fat tissue in many areas, in other fields the muscle fibers persisted but were most

patches of fibrosis throughout the myocardium, and the muscle cells themselves showed fresh patches of acute degeneration. Also there was con-

FIGURE 1

abnormal. Some were hypertrophied, and others extremely atrophic (Fig 1). There were foci of considerable infiltration of fat tissue, not uncommon in elderly people but most unusual in a man twenty-

FIGURE 2

fibrosis. The picture was typical of pseudohypertrophic muscular dystrophy.

There have been a number of reports of severe sclerosis of the myocardium in patients with muscular dystrophy. The heart showed extensive

four years old (Fig 2). I believe that we have the right to assume that this myocardial change is part and parcel of the muscular disease.

DR EDWARD F. BLAND: Did he have mural thrombi?

DR MALLORY Yes, on the wall of the left ventricle lying between the columnae carneae. They were evidently the source of the emboli.

DR BAUER Did he have auricular fibrillation on entry?

DR MALLORY I think that the rhythm was normal. The thrombi here were ventricular rather than auricular, as they would be in auricular fibrillation.

DR BAUER Was there any vascular disease?

DR MALLORY No.

DR BAUER Can you tell us more about this type of heart?

DR MALLORY So far as I can recall, it is the only one that we have seen.

DR BAUER Tell us what others have seen.

DR MALLORY Globus¹ was the first person to report this condition carefully, as far back as 1918. Since that time various single cases have been reported, and Bevans² recently reported a pair of cases, with extensive atrophy in the myocardium and with fibrosis and with fatty infiltration, corresponding exactly to what was seen here. These changes are sometimes visible in gross, sometimes microscopically.

DR BAUER Do these patients have hypertension?

DR MALLORY I do not know.

DR BAUER I followed a fairly large group of cases of muscular dystrophy with Dr Aub at the time when they were being treated with adreno-cortical extract. A few of these patients are still being seen, but I never happened to see one with this type of heart disease. Have you any idea how often it occurs—in 1 per cent, 20 per cent or 50 per cent?

DR MALLORY I have seen no figures.

DR BAUER It must be reasonably rare, because some of the people we followed are now well over forty years of age.

DR MALLORY Dr Walter Timme, in the discussion of Dr Globus's paper, stated that this was commoner in people with acute progressive disease and who died relatively early in life than in those with the slowly progressive type, he did not give any figures, however.

DR BLAND Were electrocardiograms made in your cases, Dr Bauer? The electrocardiogram on the case we are discussing showed no abnormality, except bundle-branch block, which is misleading.

DR MALLORY There has been a note in several cases that the electrocardiographic changes were slight or entirely absent.

CASE 33312

PRESENTATION OF CASE

A sixty-five-year-old unmarried woman entered the hospital complaining of abdominal cramps.

For one year the patient had noted that she tired easily. Three weeks before entry to the hospital she had had some mild cramps in the lower abdomen. Five days before admission the pain recurred, it became worse the next day and continued until she entered the hospital. For forty-eight hours prior to entry, the crampy pain was constantly present. For three days the patient had vomited repeatedly. Nothing had been passed by rectum for four days. The patient had not urinated for two days.

The patient denied previous melena, diarrhea, constipation and genitourinary symptoms. She did state that many years previously she had had some sort of abdominal pain, which was in the midlower abdomen and spontaneously disappeared. She had had no abdominal operations.

The patient appeared acutely ill. The extremities were cold and clammy. The heart and lungs were essentially normal. The abdomen was protuberant, tense, exquisitely tender and tympanitic throughout. A fluid wave was present. Peristalsis was diminished. No spasticity or masses were present. Rectal examination revealed a small uterus and marked tenderness on motion of the uterus, no masses were felt.

The temperature was 99°F, the pulse 140, and respirations 24. The blood pressure was 130 systolic, 70 diastolic.

The white-cell count was 31,700, predominantly neutrophils. X-ray films of the chest showed a normal heart. There were linear areas of increased density at the left base. An abdominal film showed no dilated loops. There was free air beneath the right half of the diaphragm, which was high, and there was a suggestion of gas within the liver.

An abdominal tap on the day of entry produced cloudy, yellow, odorless fluid containing many pus cells and numerous gram-negative bacilli and cocci on smear. A transfusion was given, and gastric suction instituted. The temperature rose to 102°F and the patient appeared to sink into circulatory collapse, she died on the morning after admission.

DIFFERENTIAL DIAGNOSIS

DR GORDON A. DONALDSON One might guess from the length, breadth and depth of this history, particularly the past history, that this patient had entered the Emergency Ward unaccompanied by anyone who might have aided her in giving an account of herself. I got the impression on second reading that she was practically in extremis on admission and that diagnostic studies were strictly limited.

It is quite obvious that she had an overwhelming peritonitis and was in shock therefrom—and even-

tually died of peripheral circulatory collapse. The single blood-pressure reading is in discord with such a picture but may represent a relative hypotension in this patient. The abdomen was protuberant and tense, compressing the lower lung fields. Although no spasm is reported, the abdomen was exquisitely tender, and the lack of reflex spasm was probably due to her serious general condition. In spite of the fact that a fluid wave was present, tympany also existed, and this, as well as the finding of air under the diaphragm, indicates the pressure of extraluminal gas. I am rather surprised that any peristalsis was heard. Certainly the lack of bowel function can be explained on the basis of widespread peritonitis, and I should like to explain the anuria on the basis of renal hypotension, secondary to the same process. In all probability, she had been in a state of relative shock forty-eight hours previous to hospital admission.

The few remarks about the past history are not helpful. The progressive fatigue could have been due to secondary anemia. "many years previously she had had some sort of abdominal pain, which was in the midlower abdomen and spontaneously disappeared." This may have been due to any process — from appendicitis to dysmenorrhea. Perhaps I am dismissing this episode too lightly. We do know positively that the bowel habits had been regular and that she had had no urinary symptoms. This forces the conclusion that the present episode was acute and fulminating.

It is important that the initial discomfort was cramp-like and later became steady. This to me usually indicates that the organ involved was capable of peristalsis against an obstruction and that eventually there was perforation or disintegration, with local spread of the process. A tubular or a solid structure, such as an ovary, may twist on its pedicle repeatedly and finally infarct, but it is unlikely that such a process could persist over a matter of three weeks. We can also say that the organ under question probably contained gas or gas-producing micro-organisms. It is unlikely that blood-borne, gas-producing organisms, nurtured in an infarcted solid organ, would give such a picture at the end of five days.

One other point of note is the position of the pain — always in the lower abdomen. The initial sympathetic reference was into the lower abdomen, as well as the later somatic pain. The large bowel or genitourinary organs become the likeliest source of her disease.

From the x-ray films I should like to know the status of gas in the bowel and just where in the liver the air existed.

DR STANLEY M. WYMAN: This upright film of the chest shows the free air beneath the right half of the diaphragm, which is higher than usual. There appears to be some linear atelectasis in the base of the left lung field. The heart is not remarkable.

The aorta is markedly tortuous, the proximal descending portion swings far to the right, and there is calcification in the wall.

This view, with the patient lying on her side, shows the gas beneath the diaphragm to move freely over the lateral surface of the liver. I am unable to see definite evidence of the suggested gas in the substance of the liver, but the liver is not well shown on the film of the abdomen. The free gas is seen lying high and medially. There is probably fluid in the abdomen, but no evidence of dilated loops of bowel. There is a lot of opaque material scattered throughout the abdomen, much of which may lie in the bowel. There is no mention of a previous barium examination or of the patient's taking medication. This appearance raises the question of calcification in an ovarian tumor, such as a papillary cystadenocarcinoma, although the shadows are unusually dense. This question cannot be answered unless we can exclude the possibility that the opaque material was in the bowel. I can see no evidence of unusual masses.

DR DONALDSON: Air in the liver deserves special comment. It can get there by two routes. The usual course is via the biliary tree, in a retrograde fashion. Less frequently the portal blood stream conveys gas-producing bacteria, which are nurtured in the liver.

What could this have been? I am going to rule out the ureters and bladder. The uterus was small. This does not exclude it from torsion, infarction or perforation of a pyometrium. The age and marital status are compatible with spontaneous rupture of a pyometrium, but the organisms found are usually of many types and the pus is foul-smelling rather than odorless.

Torsion of a salpinx or ovarian cyst with late rupture should always be considered in an elderly patient, but it seems unlikely that free gas would be present within the abdomen and that the peritoneal fluid would show on smear gram-negative bacilli and cocci.

Could she have had a pancreatitis with ascites to throw her into such a state of collapse? I should have expected the collapse to have occurred days previously.

Appendicitis in elderly people rarely causes a textbook history, and epigastric symptoms are often lacking, particularly if there have been previous attacks. Inflammation of a Meckel's diverticulum, with perforation, seems unlikely since the pain was always in the lower abdomen.

Could this patient have passed a gallstone three weeks previously, which was wafted down the small bowel with mild symptoms and eventually became lodged in the large bowel? She gives no history of biliary dysfunction, and usually these stones become stuck in the region of a Meckel's diverticulum or at the ileocecal valve. If they do not cause obstruction and perforation in the small bowel, they should

pass through the large intestine. On the other hand, a spontaneous cholecystojejunostomy fistula is the most usual route of entry of gas within the liver shadow.

Against the diagnosis of diverticulitis of the large intestine with perforation is the lack of previous history of bowel difficulties, particularly constipation. Usually there is a long story of poor bowel habits, and in 18 per cent of Dr. Smithwick's* series there was a story of bleeding by rectum. The patient could have had leakage through a diverticulum with local abscess formation three weeks previously, and then, five days before admission, a fresh burst from the abscess, with the fatal result that so often follows a second peritoneal insult.

This patient probably had a tumor of the descending colon that had caused mild obstructive symptoms for three weeks and had finally ruptured. In disagreement with this diagnosis is the fact that there was no really dilated bowel by x-ray study. Three weeks of subacute intestinal obstruction should result in some degree of bowel dilatation, particularly in the presence of terminal peritonitis. Also, the pus obtained at tap was odorless. This bothers me considerably, although it is possible to obtain odorless pus from some cases of large-bowel perforation, such as when the appendix is involved. Certainly, perforation of such a tumor would result in free air within the peritoneal cavity, and by a pyelephlebitis, gas-producing organisms might have been carried to the liver.

CLINICAL DIAGNOSIS

Generalized peritonitis (cause unknown)

DR. DONALDSON'S DIAGNOSIS

Peritonitis, probably secondary to carcinoma of colon

ANATOMICAL DIAGNOSES

Benign peptic ulcer of stomach, with perforation and mesenteric abscess

*Smithwick R. H. Experiences with surgical management of diverticulitis of sigmoid. *Ann. Surg.* 115:969-985, 1942.

Perforation of mesenteric abscess, with generalized peritonitis

Congenital anomalies: right-sided aorta and anomalous origin of left subclavian artery

Arteriosclerosis

Leiomyomas of uterus

Carcinomas of ileum

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY. Dr. Donaldson was quite correct in predicting that the peritonitis in this case was due to a perforated viscus. He was also right in suggesting that the leakage occurred in two stages — first, local abscess formation and, later, rupture of the abscess with generalization of the peritonitis. He was completely wrong, however, in his localization of the process. Despite the fact that all the symptoms were lower abdominal, the primary lesion was in the stomach. We found a benign peptic ulcer high up on the posterior wall, only 7 cm. from the cardia, and close to the greater curvature. An abscess 7 cm. in diameter was present in the gastrocolic ligament that had a thick fibrous wall and was evidently of some weeks' duration. The abscess communicated through two small perforations with the lumen of the stomach through the base of the ulcer and with the general peritoneal cavity.

There were numerous incidental findings. The major arterial trunks were anomalous. The right common carotid and subclavian arteries arose separately from the aortic arch, the left subclavian artery was low and came off at the junction of the arch and descending aorta. The arch itself turned directly backward instead of crossing the vertebral column, and the descending aorta lay to the right of the trachea and of the vertebral column. Evidently there had been no cardiac embarrassment from this dextroposition, since the heart was of normal size.

The uterus contained several small fibroids and the ileum several carcinoid tumors, none of them large enough to have caused intestinal obstruction.

EXUDATIVE TONSILLITIS AND PHARYNGITIS OF UNKNOWN ETIOLOGY

THE Commission on Acute Respiratory Diseases is again calling attention to a group of acute upper-respiratory-tract infections of unknown origin that it is important to differentiate from streptococcal infections of the throat.* In the course of studies on acute respiratory diseases carried out over a three-year period at Fort Bragg these workers encountered many cases of exudative tonsillitis and pharyngitis in which beta-hemolytic streptococci could not be incriminated as the causative agent. Indeed, it was quite conclusively demonstrated that about half the cases of tonsillitis and pharyngitis that they studied had neither bacteriologic nor serologic evidence of streptococcal infection.

*Commission on Acute Respiratory Diseases. Exudative tonsillitis and pharyngitis of unknown cause. *J. A. M. A.* 133:588-593, 1947

Clinically, a comparison of the cases of unknown cause with those that were proved to be of streptococcal origin revealed distinctive characteristics of these groups as a whole, but the clinical findings were of little help in the differential diagnosis of individual cases. In general, the streptococcal infections had a more acute onset than the cases of unknown etiology. In the latter, chilliness, feverishness, headache and malaise — symptoms indicating systemic reaction — were slightly less frequent. On the other hand, the nonstreptococcal infections tended to involve the lower respiratory tract, as evidenced by the greater incidence of hoarseness, productive cough and pain in the chest. Sore throat and dysphagia were encountered with about equal frequency in both types of cases.

Physical examination also revealed some features that were helpful in the differential diagnosis. The patients in the streptococcal group gave the appearance of a more serious illness, they often showed diffuse redness of the mucous membranes of the palate, tonsils and posterior pharyngeal wall, and in the majority of them some edema of these tissues was also evident. Enlarged and tender lymph nodes, in particular, were more frequent in the cases of streptococcal infection. When caused by the streptococcus the tonsillar or pharyngeal exudate was usually yellow and extensive. By contrast the exudate seen in the nonstreptococcal cases was white or gray, was often of pinhead size and was frequently distributed over enlarged follicles of lymphoid tissue on the posterior pharyngeal wall.

The white-cell counts were also of some value in the differential diagnosis. Leukocytosis was a feature chiefly of the streptococcal cases, in which the average total count was about 13,000 with 79 per cent neutrophils, as compared with an average of about 9,000, with 67 per cent neutrophils, in the nonstreptococcal cases. Although both diseases are of short duration, with fever generally lasting less than four days, the maximum temperature tended to be higher in the streptococcal cases than in those of unknown cause, the average was 102.5 in the former, and 101.7°F in the latter.

Although the differential diagnosis between the streptococcal and nonstreptococcal cases can ordinarily be made on clinical grounds, on the basis of

the criteria mentioned, cultures or serologic methods must be employed for accurate diagnosis. It is particularly important to differentiate these forms because the nonstreptococcal infection is a benign disease without important complications, whereas the streptococcal infections may give rise to serious and crippling sequelae. Intelligent management of such cases, therefore, requires cultural and serologic confirmation of the diagnosis.

The finding of streptococci in throat cultures may not always be adequate to establish a diagnosis, since normal subjects and those with undifferentiated respiratory infections may harbor streptococci, without the production of antibodies. Throat cultures from such persons, however, usually reveal only small numbers of streptococci, whereas the cultures in the true streptococcal infections, in which an antibody response is elicited, frequently yield a predominant growth of hemolytic streptococci.

The cause of the type of exudative tonsillitis and pharyngitis that the Commission on Acute Respiratory Diseases described is unknown. No single bacterial agent could be incriminated, and it was presumed to be a disease of nonbacterial origin. On epidemiologic grounds, it was thought that these cases might represent a variant of "epidemic undifferentiated acute respiratory disease." The incidence of this form of infection in civilian practice is not known, but it has been encountered with varying frequency, particularly in areas where epidemics of streptococcal infections have not been frequent or extensive. The suggestion is advanced that, because of the generally mild character of the disease, its short duration and the freedom from complications, this condition should be sought for among patients treated at home rather than among those treated in hospitals.

NONTUBERCULOUS PULMONARY CALCIFICATION

The methods generally used in surveys designed to discover cases of tuberculosis in its early stages and those intended to determine the probable incidence of the disease in the community include roentgenograms of the chest and tuberculin tests. The occurrence of demonstrable lesions in x-ray films, particularly areas of calcification with en-

larged hilar nodes, has traditionally been considered to be evidence of tuberculous infection, and such lesions are usually accompanied by positive cutaneous reactions to tuberculin.

Recent surveys, particularly those in certain sections, such as Kansas City, Missouri, and Tennessee, have revealed a large number of persons with areas of calcification in their lungs and negative tuberculin tests.¹⁻⁵ Such a situation is ordinarily interpreted as evidence of anergy and is encountered in cases of miliary tuberculosis and sometimes during other active acute infections, notably measles. It is known, however, that certain other conditions, such as coccidioidomycosis in the active or end stage, may give similar roentgenographic findings, but the latter disease could not account for the findings in the recent studies.

Extensive studies in several areas among school children and student nurses have indicated a close correlation between the incidence of those who are tuberculin negative and x-ray positive and that of positive reactors to histoplasmin.¹⁻⁷ This is particularly close in persons with disseminated areas of calcification in the lungs. The findings suggest that histoplasmosis or some other disease that produces pulmonary lesions and results in sensitivity to histoplasmin is prevalent. Interestingly enough, the regions where the incidence of x-ray-positive, tuberculin-negative and histoplasmin-positive cases is the highest correspond to those from which proved cases of histoplasmosis have been reported. Among student nurses the area of highest incidence was found in the eastern central states, and the frequency of the occurrence of such cases diminished progressively in proportion to the distance from this area.⁸

The surveys that included histoplasmin skin tests have also resulted in the discovery of cases of active pulmonary disease among children in Kansas City, Missouri, and among student nurses in several states.⁹ The pulmonary lesions simulated those of tuberculosis and eventually went on to calcification. There are no known criteria for differentiating these roentgenographic lesions and those of tuberculosis.

A review of the reported cases of histoplasmosis suggests that this is a highly fatal disease.¹⁰ If the finding of positive reactors to histoplasmin is inter-

puted as evidence of infection with *Histoplasmosis capsulatum* or with some related organism, such a disease must be considered as existing chiefly in a benign and unrecognized form. Most workers who have been intimately concerned with these studies, however, are cautious in the interpretation of their findings,⁵ partly because of the reports of cases of known and active histoplasmosis in which the skin tests with histoplasmin were negative^{9,10} and particularly because of the demonstration of marked cross reactions with histoplasmin in animals with experimental mycotic infections, including blastomycosis, coccidioidomycosis and moniliasis.^{9,11} The negative histoplasmin tests during active infection may be interpreted as evidence of anergy and are probably analogous to negative tuberculin tests in cases of miliary or other active forms of tuberculosis, they have been observed in severe disseminated and fatal cases of histoplasmosis.^{9,10}

Histoplasmosis is not known to occur in New England, but it has been reported from areas as close as New York and Washington, D C. Unexplained pulmonary lesions, including disseminated areas of calcification, are encountered, however, that are not unlike those that have been described in Kansas City, Missouri, and Tennessee, which in those areas are associated with negative tuberculin reactions and positive cutaneous histoplasmin reactions. The possibility that some of these lesions in tuberculin-negative persons are the results of mycotic infections should be considered, particularly when other causes of disseminated pulmonary lesions can be excluded.

MASSACHUSETTS MEDICAL SOCIETY MEDICAL CARE FOR OLD-AGE ASSISTANCE

The following communication regarding rule relating to authorization and control of medical care for old-age assistance has been sent to all physicians in Boston by the Bureau of Old Age Assistance. It appears to be of sufficient importance to merit reprinting in the *Journal*.

Payment for doctor's service will be approved at a rate not to exceed \$3 00 for a home visit and \$2 00 for an office visit unless unusual circumstances warrant a higher payment.

Doctors are requested to notify the department immediately, to answer and return the medical inquiry promptly and to send bill to the recipient within fifteen days. Otherwise there may be a delay in payment.

Bills for excessive amounts and for an excessive number of visits and tardy bills are subject to review by the Medical Advisory Committee.

A rate not to exceed \$5 00 a day for hospital care will be approved subject to the department's agreements with the hospitals. This rate includes all care, including service of a physician. It is expected that recipients in need of hospital care will obtain care in the large incorporated hospitals where adequate and economical service can be obtained.

Each recipient of old age assistance proved eligible for the medical assistance will be given an additional grant in accordance with the need. The recipient is directly responsible to the doctor and the hospital for payment of the obligation incurred.

JOSEPH GARLAND, Secretary

DEATHS

DAVIS — Max Davis, M D., of Brookline, died April 30. He was in his forty-seventh year.

Dr Davis received his degree from Harvard Medical School in 1925. He was assistant professor of obstetrics and gynecology, Boston University School of Medicine, and senior visiting physician, Gynecological Staff, Beth Israel Hospital, and was a diplomate of the American Board of Obstetrics and Gynecology, as well as fellow of The American College of Surgeons.

His widow survives.

DUTTON — Frank K. Dutton, M D., of Springfield, died June 28. He was in his fifty-sixth year.

Dr Dutton received his degree from Tufts College Medical School in 1915. He was a fellow of the American College of Surgeons and the American Medical Association.

His widow survives.

GORHAM — George H. Gorham, M D., of Boston, died on March 12. He was in his seventy-seventh year.

Dr Gorham received his degree from Tufts College Medical School in 1903.

CORRESPONDENCE

SALT-FREE BREAD

To the Editor: In view of the known importance of low salt diets in the treatment of cardiac failure and also of hypertension, it appears to be important to call the attention of physicians in the vicinity of Boston to the fact that salt-free bread is now available through Betty Bakelite Incorporated, at one of their local stores (235 North Beacon Street, Brighton). The manager informs me that if the demand for this bread becomes great enough it will be supplied through their various stores throughout the city.

THERAPEUTIC ABORTION FOLLOWING RUBELLA

To the Editor: The progress article on rubella in the June 19 and 26 issues of the *Journal* was extremely interesting. The scientific approach to the etiology, course, differential diagnosis, complications, treatment and prevention was admirable.

The last three pages of the article, however might just as well have been deleted from a scientific journal of medicine. The discussion of therapeutic abortion in cases of rubella in early pregnancy was highly philosophical and thus controversial and definitely not scientific. In addition anyone with the slightest training in logic can discern numerous violations of ordinary common sense in this portion of the article.

Regardless of one's position in this disputed matter I repeat that discussions of this type do not belong in a scientific medical journal. If one has opinions or strong feelings on morality, euthanasia, the Bible or witches such opinions, it seems to me, should not be included in medical articles.

ALBERT E. PAGANINI, M.D.

197-02 Linden Boulevard
St. Albans, New York

Dr. Paganini's letter was referred to Dr. Conrad Wesselhoeft, the author of the article in question. His reply is as follows.

To the Editors: The criticism of the discussion of abortion in the progress review on rubella brings to mind a letter on the subject in the *British Medical Journal* (Barry W. K. Correspondence Rubella and pregnancy *Brit. M. J.* 1 423, 1947) that goes far beyond discerning 'numerous violations of ordinary common sense.' This English physician refers to abortion as murder and insists that as such this operation is never justifiable and, in the case of rubella in early pregnancy, is a 'massacre of the innocents.'

The advancement of medical knowledge exerts a profound influence on public opinion and on the enactment of laws pertaining to human welfare. The mission of the medical profession is concerned not alone with scientific research and administration to the sick but also with preventive medicine. The carrying out of any preventive measures is dependent on enlightened public opinion and frequently involves overcoming deep-rooted beliefs. Vaccination against smallpox is a typical example.

In the discussion of the application of newer knowledge of rubella in early pregnancy, it seemed appropriate to bring out the historical background. The ancient concept that congenital defects resulted from witchcraft led me quite naturally to the original biblical commandment and to the evolution of laws pertaining to it. This approach assailed an ancient tenet that has been rendered obsolete through public opinion and the enactment of radical changes to the law.

The statutes relative to abortion have been amended to conform to our newer knowledge of disease without endangering the intent of the original law. After presenting the possibilities of congenital deformities following rubella in early pregnancy and the resulting unfortunate detriment to future pregnancies, I emphasized the purpose of the existing law and finished with an appeal for the consideration of a further amendment to cover this particular situation for the betterment of suffering humanity. The fundamental purpose of religion, medicine and the law is to help mankind. When this purpose fails, it is the fault of the frailties of human nature, and correction is due.

CONRAD WESSELHOEFT, M.D.

315 Marlboro Street
Boston 16

BOOK REVIEWS

Agnesia, Apraxia, Aphasia Their value in cerebral localization By J. M. Nielsen, M.D. Second edition completely revised 84, cloth, 292 pp., with 59 illustrations. New York: Paul B. Hoeber Incorporated, 1946. \$5.00.

The elucidation of the many problems associated with speech defects has long been of interest to the medical profession. From the time of Broca through the work of Head in England and Starr and Mills in America, there has been

a continued interest in this problem. In recent years the outstanding investigator has been the author of this monograph. The first edition was published privately in 1936, when the enthusiasm for the study of aphasia and allied conditions was not great. The matter, however, was kept open by the continued investigations of Dr. Nielsen and his first publication did not fall on sterile ground. Indeed it was welcomed in many places where research was going forward. Now ten years later he has expanded the book into a second edition of increased usefulness.

In various chapters he covers a brief history of the knowledge of aphasia, apraxia and agnosia. He then outlines the theories regarding causation of these conditions and details each in a separate section of the book. After giving the methods of examination used clinically in the elucidation of the signs of speech defects, he presents the bulk of his monograph in a careful analysis of the pathologic material observed by him over a period of many years and carefully correlated with the clinical evidence in each case. The volume closes with an appendix on nomenclature and a selected bibliography.

The book will be of use to the clinical neurologist who has to meet the acute problem of aphasia to the neurologic surgeon who needs to know the aphasic syndromes as an aid to localization and to the growing numbers of investigators who are attempting to untangle one of the most complicated of all problems in neurology. There is still much to learn, but no better basis for advancing knowledge can be found than the text provided by Dr. Nielsen in the present edition of an outstanding monograph.

Carbohydrate Metabolism Correlation of physiological biochemical and clinical aspects By Samuel Soskin, M.D. and Rachmiel Levine, M.D. 8" cloth 315 pp. with 42 tables. Chicago: University of Chicago Press 1946. \$6.00.

The authors state in the preface that 'the volume is intended to serve as a correlative text for the teaching of carbohydrate metabolism to students of physiology, biochemistry and medicine.' The average medical practitioner who consults the book may find a large part of it bewildering. He may feel beyond his depth as he reads the early chapters dealing with the 'enzymatic machinery' and other matters concerned with intermediary metabolism. Also, he will probably find many of the ideas that he has cherished regarding metabolism flatly contradicted.

The following quotation illustrates the iconoclastic attitude and diction of the authors:

It is clear that neither the low R.Q. of diabetes nor the failure of the R.Q. to rise following the administration of sugar constitutes evidence for a lack of ability to oxidize carbohydrate. One must conclude that chemical balance studies offer neither theoretical nor actual support for the R.Q. as a measure of dissimilation. Since no other validation of the R.Q. is available at the present time one must go further and say that there is no evidence that the R.Q. is a measure of dissimilation.

Concerning the dextrose nitrogen ratio they write, "We may summarize the present knowledge by saying that whatever its empirical usefulness the figure of 44-55 per cent commonly used in metabolic and nutritional work to calculate the carbohydrate equivalent of protein has no real basis of fact." In reference to ketosis they state:

It is thus no longer proper to speak of anti ketogenesis in the sense so long employed by clinicians by which they actually meant ketolysis (ketone oxidation). In view of present knowledge the various ketogenic, anti ketogenic ratios which have been used to calculate the amounts of carbohydrates necessary for oxidation of the ketone bodies must be regarded as being without any real significance.

Soskin has been a strong proponent of the theory that the fundamental metabolic defect in diabetes is overproduction of sugar contrary to the theory popularly held in the past that there is loss of the capacity to utilize sugar. The work that he and his collaborators have done to support this view and to develop new ideas regarding carbohydrate metabolism is discussed in detail. In presenting controversial points Soskin has tried to be impartial but his critics may claim that he has not always succeeded.

The direct clinical applications of the book are limited. Indeed, such clinical recommendations as the use of the intravenous glucose-tolerance test as a criterion of liver function and the opinion of the authors concerning the alleged need for large amounts of sugar or other carbohydrates in the treatment of diabetic coma are not likely to receive general acceptance.

Progress in medical practice cannot be made unless there is readiness to relinquish unsound concepts. Soskin and Levine will give a healthy stimulus to those whose ideas are fixed by prejudice or misinformation.

The American Hospital. By E. H. L. Corwin, Ph.D. Studies of the Committee on Medicine and the Changing Order, New York Academy of Medicine. 8°, cloth, 226 pp. New York: The Commonwealth Fund, 1946. \$1.50.

In this special monograph Dr. Corwin presents a factual analysis of existing hospital conditions in the United States. He points out that although the present hospital plant represents an investment of five and a half billion dollars it has reached this magnitude through unorganized effort and not by conscious planning.

The first chapter reviews briefly the history of hospital information from the time of the first list, compiled by Dr. J. M. Toner in 1873, to the present. The second discusses the hospital domain, embracing the development, types and ownership of hospitals. It is well documented with charts and tables. The statistics for 1943 show a total of 6655 hospital institutions of all kinds in the country, with a total bed capacity of 1,649,254 — or about 1 hospital bed for every 80 persons in the gross population. One of every 10 persons in the United States is admitted annually to a hospital. The third chapter deals with hospital finance and analyzes plant assets, investment sources, including the increasing governmental participation, operating costs and income from various sources. The succeeding chapters discuss the distribution and utilization of hospital facilities, the hospital as employer and as a training ground, personnel and administration, medical service and the outpatient department and the housing of hospitals.

The uneven distribution of hospital facilities is analyzed, and the effect of urbanization and industrial centralization is emphasized. Efforts to increase and improve hospital facilities, including prepayment plans, Blue Cross, workmen's compensation, inclusive-rate and moderate-rate plans, are gone into in detail. Medical service is discussed from the viewpoints of organization and standardization.

In the final chapter, under the heading "Retrospect and Prospect," an attempt is made to summarize the significant facts brought out in the previous chapters and to examine the future of the hospital. The topics discussed include the importance of the general hospital, dependence of local governments on voluntary hospitals, nonprofit basis of hospital investment, size of hospitals, rising costs and cost accounting, sources of revenue, utilization of hospitals, domiciliary care of sick patients, chronic and convalescent, estimate of postwar needs, research, public-health and preventive medicine and pathometry, or the use of hospital statistics.

A list of selected references is appended to each chapter, and a good index concludes a well published volume. It contains a mass of authoritative data, and is recommended for all medical libraries as well as public libraries and hospital administrators.

The Second Forty Years. By Edward J. Stieglitz, M.D. With a foreword by Anton J. Carlson, Ph.D., LL.D., M.D., Sc.D. 8°, cloth, 317 pp., with 18 figures. Philadelphia: J. B. Lippincott Company, 1946. \$2.95.

In this semipopular book Dr. Stieglitz presents a guide to longer life and considers the problems incident to the aging of the person over forty. The biology and hazards of senescence are comprehensively discussed. It is interesting to note that the average life span has increased from twenty-one years at the time of the Holy Roman Empire to sixty-six years in 1944.

The rate of aging is rapid from birth to forty years, and slow from forty to a hundred years, on a chart it is almost a straight drop to twenty years, and about a flat line from fifty years on. Statistical graphs point out an interesting

situation in 1900, persons of sixty-five years and over comprised 4.1 per cent of the population, in 1940, the figure had increased to 6.8 per cent, and it is estimated that in 1980 the percentage will have increased to 14.4. The percentage of persons under five years of age during the same periods are, respectively, 12.1, 8 and 6.4. The life expectancy from birth was forty years in 1850, forty-seven years in 1900 and sixty-three years in 1940, and if the increase continues at that proportion to 1980 the span may reach seventy to seventy-five years. These statistics reveal a decline in the birth rate and an increase in the life span, a serious problem.

There are special chapters on heart disease, high blood pressure, cancer, nutrition, sex and age, mental changes and the wise use of leisure. The final chapter discusses the relation of an aging people to society.

The book contains practical advice for the elderly on how to eat, play, think and face the threats of chronic disease. It is an unusual, outstanding treatise by a competent medical authority and should be in all libraries, medical and public. The volume is well published in every way.

The Chest. A handbook of roentgen diagnosis. By Leo C. Rigler, M.D. 8°, cloth, 352 pp., with 338 illustrations. Chicago: Year Book Publishers, Incorporated, 1946. \$6.50.

The greatest limitation in the atlas type of presentation of radiologic texts has been the poor quality of reproduction. In this volume the problem is well handled in handbook form. The illustrations are numerous and of good quality and are captioned by descriptions and interpretations of specific examples of roentgenologic changes in diseases of the lungs, bronchi, mediastinum and pleura. Primary heart changes and lesions of the thoracic cage have been omitted since they are outside the scope of the book. The pathological and physiologic aspects of diseases of the chest are discussed only so far as they are relevant in roentgenologically evident lung changes.

The presentation is sound, and the descriptions are lucid. The organization for reference, however, is poor, and the book is not inclusive enough for a reference on chest disease.

In the field of chest diagnosis, in which the roentgenologic interpretation stands unrivalled as the most rewarding single procedure, the internist should find this book an elucidating text and a helpful guide. The student of roentgenology will also find it excellent for preliminary orientation.

Mongolism and Cretinism. A study of the clinical manifestations and the general pathology of pituitary and thyroid deficiency. By Clemens E. Benda, M.D. 8°, cloth, 310 pp., with 101 illustrations and 48 tables. New York: Grune and Stratton, 1946. \$6.50.

This monograph is based on the study of a large series of cases of mongolism and cretinism seen at a state school for mental deficiency. The study covers all aspects of both diseases in an adequate, scholarly manner and thus brings to the attention of physicians a complete review of present knowledge of the two distressing conditions. Most of the book deals with mongolism, and the conclusions are based on the observations of more than 300 patients. Dr. Benda adds greatly to knowledge of the hereditary aspects of the problem, as well as its relation to the pregnancy of the mother and the order of birth. He believes that mongolism is due to deficiency of the anterior portion of the pituitary gland — a point that is not conceded by many investigators. Factors other than endocrine are needed to explain all the aspects of mongolism. Moreover, treatment by glandular preparations has not been satisfactory, even in Dr. Benda's hands.

The format of the book, the illustrations and the bibliography are beyond criticism. The monograph will be of particular interest to pediatricians and obstetricians.

Introduction to Surgery. By Virginia K. Frantz, M.D., and Harold D. Harvey, M.D. 12°, cloth, 216 pp. New York: Oxford University Press, 1946. \$2.50.

This is a pocket-sized volume with an excellent index and extensive up-to-date references. Well adapted for the beginner, it is concise and clear and presents the elements of surgery in a simple, readable manner. It is especially recommended for medical students.

Number 6

SEPTICEMIA DUE TO *SALMONELLA ENTERITIDIS*

MYLES P. BAKER, M.D.,* AND JOSEPH H. BRAGDON, M.D.†

BOSTON

THE genus *Salmonella* comprises a large number of gram-negative enteric bacilli pathogenic to both man and animals. They are grouped together by reason of similarities in biochemical behavior, but more definitively by reason of the specific antigens that they possess in common. Differentiation within the group is based on variations, often minor, in these biochemical and antigenic characteristics. The National *Salmonella* Center has available for distribution over one hundred and sixty different species or types, not all of which, however, have yet been proved pathogenic to man.¹

In the accepted classification *Salmonella enteritidis* falls into Group D, for its somatic antigens are identical with those of *Eberthella typhosa*. In most respects, however, it more closely resembles other members of the genus. It has a wide natural distribution, having been isolated from a variety of animals, both wild and domestic, in many parts of the world. Human infections with *S. enteritidis* usually arise from the ingestion of uncooked material from infected animal sources. Persons thus contracting infection with this organism characteristically develop nonbloody and nonpurulent diarrhea accompanied by varying degrees of abdominal pain, nausea and vomiting. Prostration may be alarming, but the symptoms are short lived, and recovery is complete.

S. enteritidis was first isolated in 1888 by Gärtner,² who recovered it following an outbreak of acute gastroenteritis that had affected 58 persons, all of whom had eaten meat from an emergency-slaughtered cow. Known since that time as Gärtner's bacillus, it has frequently been responsible for similar outbreaks of food poisoning. In 1926 Kinloch et al.³ reported an outbreak of acute gastroenteritis in Aberdeen affecting 497 persons, all of whom had drunk milk subsequently traced to a single cow. *S. enteritidis* was isolated from the cow's udder, from samples of the milk and from the stools of many of the victims. According to Topley and Wilson,⁴ *S. enteritidis* was responsible

for over 12 per cent of all outbreaks of food poisoning produced by *Salmonella* in England between 1923 and 1939. It was exceeded in incidence only by *S. typhimurium*. An analysis by Edwards and Bruner⁵ of data accompanying organisms submitted to the National *Salmonella* Center indicates that it has been somewhat less frequent in the United States.

Although *S. enteritidis* has definite invasive powers for the tissues of mice and of other laboratory rodents, in human infections it is not prone to penetrate beyond the intestinal mucosa. It is true that Gärtner originally isolated the organism from the spleen of the one fatal case in his series, but comparable cases with adequate bacteriologic confirmation are extremely rare. The literature contains several reports of isolated cases in which *S. enteritidis* was reputedly recovered from the blood stream, but it is likely, as Topley and Wilson⁴ point out, that many of these were actually cases of infection with *S. dublin*, whose differentiation is of comparatively recent date. Confusion caused by failure to distinguish the two organisms occurred as late as 1944, when, in an article entitled "*Bacterium enteritidis* Septicaemia," McDonald⁶ reported 3 cases of prolonged fever—one of which was fatal—in Indian soldiers. In each case *S. dublin* was isolated from the blood.

Authenticated cases in which *S. enteritidis* has been recovered from sites other than the gastrointestinal tract are, nevertheless, to be found. Of a thousand consecutive *Salmonella* organisms (exclusive of *E. typhosa*) submitted to the New York *Salmonella* Center thirty-one were identified as *S. enteritidis*. Seligman, Saphra and Wassermann,⁷ in analyzing this material, reported that in 25 cases the organism had originally been isolated from stools, but that in 4 it had been recovered from the blood and in 2 from abscesses, in 1 it had been the cause of a purulent meningitis. Clinical case reports in which *S. enteritidis* has exhibited invasive qualities are confined largely to infants, among whom the organism appears to have a predilection for the meninges. Guthrie and Montgomery⁸

*Associate physician, Massachusetts General Hospital.
†Instructor, Department of Pathology, Harvard Medical School.

reported a nursery epidemic involving 27 infants. In 15 cases the organism penetrated the body beyond the intestinal tract, producing a purulent meningitis in 10.

Among adults *S. enteritidis* appears to gain access to the blood stream only when the natural resistance of the host has been lowered by concomitant diseases. Savino and Menendez⁹ identified the organism following isolation from the blood of 10 soldiers in the Chaco War. Clinical data in their paper are extremely scanty, but the patients were apparently suffering from a condition similar to typhoid fever. The authors emphasize the point that the troops were severely debilitated by other conditions. Huang et al.¹⁰ reported 17 cases of bacteremia due to *S. enteritidis* among the beggars of Peking. In 9 cases the infection occurred simultaneously with relapsing fever, and in all the authors emphasized the poor general health of the patients.

During the fighting in the Buna-Sanananda area of New Guinea in December, 1942, and January, 1943, a considerable but unknown number of American and Australian troops became infected with *S. enteritidis*. In several cases the organism penetrated beyond the gastrointestinal tract, producing fevers and suppurative processes of considerable clinical interest. It is the purpose of this paper to report 6 cases among American troops, all of whom were seen at a United States Army general hospital at various times following the close of the campaign.*

CASE REPORTS

CASE 1 About January 29, 1943, while in combat at Sanananda, this patient developed fever and headache. He was hospitalized. Because of the finding of a positive smear for malaria (type undetermined) and an enlarged spleen, he was given antimalarial therapy. A temperature up to 105°F continued. At the end of the 1st week of fever the left testicle became painful, simultaneously with the onset of a mild degree of frequency and dysuria.

The patient was evacuated to Australia and on February 24 was admitted to the hospital, exhausted and apathetic. His chief complaints at that time were diarrhea and testicular pain. The temperature was 102.4°F, and the pulse 90. Physical examination revealed an enlarged spleen and a swollen, tender left epididymis. Examination of the blood disclosed a hemoglobin of 60 per cent and a white-cell count of 7000, with a normal differential count. Smears were negative for malaria. The urine persistently showed many polymorphonuclear cells in the sediment. The stools were liquid but not purulent. Although no diagnosis was made, sulfathiazole was given, following which the fever, diarrhea and epididymitis subsided.

On March 3 the patient first complained of pain over the fifth costal cartilage on the right, and during the following 10 days a subcutaneous mass gradually developed in this area. The mass was firm and tender, and the overlying skin was reddened. It was aspirated and from the thin purulent material obtained *S. enteritidis* was isolated in pure culture. The general condition had continued to improve, but on April 7 the patient again began to have daily elevations in

temperature. The right femoral lymph nodes became moderately enlarged and tender. The white-cell count rose to 22,850, with 31 per cent eosinophils, but this was presumably related to the subsequent appearance of hookworm ova in the stools. A blood culture taken on April 13 grew *S. enteritidis*, but one taken on the following day remained sterile. A stool specimen submitted on April 24 was positive for the same organism, and sulfadiazine therapy was begun. The drug was continued for 3 weeks and was associated with a steady decrease in the temperature and a reduction in the size of the femoral nodes. *S. enteritidis*, however, continued to be passed in the stools. The patient was given sulfa guanidine for 16 days, after which repeated cultures remained negative.

The only problem then remaining was a chronic draining sinus on the chest wall, which had been present since a biopsy of the abscess had been taken in April. On August 25 the sinus was explored. It was found to lead into a cavity in the fifth costal cartilage. Six centimeters of cartilage was removed. The wound healed slowly, continuing for some time to give positive cultures for *S. enteritidis*. The patient was not returned to duty until November, almost 10 months after the appearance of the first symptoms.

In March, 1944, the patient was readmitted to the hospital for an unrelated condition. The sinus on the chest wall had remained closed. Two stool cultures were examined for *S. enteritidis* with negative results.

CASE 2 This soldier, from the same company as the patient in Case 1, had been in the combat area at Sanananda from December 28, 1942, to January 9, 1943. On January 20 he had his first chill and a fever that did not respond to the usual therapeutic doses of quinine. He was therefore admitted to a hospital, where, because of an enlarged spleen and a smear that was said to have been positive for *Plasmodium vivax*, quinine was continued in large doses. The patient became progressively worse, developing a severe diarrhea, a painful right epididymis and, eventually, delirium. He was evacuated to Australia and admitted to the hospital on February 24.

On admission he was febrile. The spleen was enlarged and tender. The right epididymis was markedly swollen and tender. The white-cell count was 5650, with a normal differential. No malaria parasites were found. The patient was moderately anemic, and there was a mild pyuria. He was treated supportively. The diarrhea soon relented, but left sided pleuritic pain developed. Rales were heard over the left lower lobe, and an x-ray film confirmed the diagnosis of pneumonia as well as showing a small pleural effusion. Sulfathiazole was given without effect. Not until March 25 did the patient become afebrile — for the first time in 9 weeks — and begin to improve in weight and well-being. The epididymitis subsided spontaneously.

On April 23 he complained of the sudden onset of severe pain low in the back. About 2 weeks later chills and fever reappeared. *P. vivax* was again demonstrated in the blood, but in spite of intensive antimalarial therapy the fever continued for 4 or 5 weeks. Physical and x-ray examination revealed no localizing signs of infection in the lumbar vertebrae. Because of experience with other cases of infection with *S. enteritidis* this organism was specifically sought in the blood, stools and urine, but with negative results. A specimen of serum drawn on May 30, however, agglutinated the organisms recovered from other cases of infection in dilutions of 1:320.

By June 15 the second febrile episode had terminated, and the patient began to regain the 25 pounds of weight that he had lost. He continued, however, to complain of severe low-back pain, and the sedimentation rate remained elevated. It was not until August 16 that there were any radiographic changes to explain these phenomena. At that time definite narrowing of the intervertebral spaces between the fourth and fifth lumbar vertebrae, with partial destruction of the posterior portions of the vertebrae, was observed. In view of the clinical course and the high agglutinating titer of the serum it was believed that *S. enteritidis* was the organism responsible for the bone infection. The patient was immobilized in a plaster shell, with considerable relief of pain, and evacuated to the United States. The subsequent course of the illness is not known.

*Fourteen similar cases¹¹ were observed in an Australian general hospital at Port Moresby from January to March, 1943. The patients had been evacuated from the same small combat area from which the following cases had been derived. The predominant clinical picture was that of sustained fever, with urinary-tract infection, septic complications, such as abscess, *S. enteritidis* was recovered from the blood, urine, stools and abscesses. In 1 case the soldier had been out of the combat area for a month before the onset of the febrile illness.

CASE 3 In early January 1943, while in a field hospital near Buna convalescing from a minor gunshot wound received a month previously, this patient had diarrhea and fever for 4 or 5 days. On January 10 malaria parasites (type undetermined) were found in the blood but despite specific therapy the fever continued unabated for another 12 days. At that time an area of local tenderness on the right lower chest anteriorly was noted. Occasionally a sharp pain was present in the same region. All symptoms however including the fever gradually subsided.

In February cloudy vision developed in the left eye, and the patient was evacuated to Anstralla, entering the hospital on the eye service on February 25. Examination revealed fine vitreous opacities with an area of acute chorioretinitis. The eye slowly responded to local treatment.

It was not until April 1 that attention was directed to a tender mass overlying the costochondral junction of the right eighth rib. This corresponded in location to the previous attack of pain and tenderness. In other respects the patient felt entirely well and was afebrile. On April 25 the mass was aspirated, yielding a small amount of purulent material from which *S. enteritidis* grew in pure culture. Three urine and six stool cultures were negative for the same organism. Sulfadiazine was given for 3 weeks, following which the mass resolved. The patient was discharged to duty in July.

CASE 4 This soldier was in combat in the Buna-Sanananda area from December 5, 1942, to February 4, 1943. His company being for a time close to that of the patients in Cases 1 and 2. During this period he had two bouts of malaria, both of which quickly responded to specific therapy and one attack of mild diarrhea for 6 days. Following the campaign his unit was returned to Australia. The patient was active on training maneuvers until March 26, when he developed pain in the left shoulder and 2 days later chills fever abdominal pain and vomiting. He was admitted to a hospital where malaria parasites were found in the blood. Despite specific therapy the temperature continued to swing daily up to 103°F. The white-cell count remained under 10,000, with a normal differential. Sulfadiazine had no effect on the fever. Finally, a tender mass appeared in the left upper quadrant of the abdomen and the patient was transferred to a general hospital on April 18.

On admission the patient was febrile. In addition to a grapefruit sized mass in the left upper quadrant a soft tender mass was palpable in the rectovesical pouch. The white-cell count was 5600. On April 22 the pelvic abscess was evacuated through the anterior rectal wall, and the left upper quadrant mass, which was found to be a well localized peritoneal abscess, was incised and drained. From the latter *S. enteritidis* was isolated in pure culture.

Following surgical drainage there was a prompt cessation of fever. Blood and urine cultures taken during the following week were sterile, but from two of several stool specimens the same organism was isolated. The patient made an excellent recovery and the surgical wound healed without evidence of residual infection. Following sulfaguanidine therapy for 11 days, *S. enteritidis* disappeared from the stools.

CASE 5 This patient was in the Buna-Sanananda area from December 25, 1942 to February 12, 1943. During that time he had no diarrhea but did have two attacks of fever both of which responded to specific antimalarial treatment. In June, while on furlough in Anstralla, he developed chills, fever and severe backache. Antimalarial treatment had no effect on the symptoms. He became extremely ill, confused and irrational. On June 26 he was transferred to the hospital.

The temperature rose almost daily to 103°F. Physical examination revealed only a palpable spleen and severe low back pain with muscle spasm. The white-cell count was 5700, with a normal differential. The urine showed moderate numbers of polymorphonuclear cells. Despite negative smears for malaria therapeutic doses of quinine and quinaquine (Atabrine) were given, but without effect on the fever. Blood agglutination studies were performed and the serum was found to agglutinate *S. enteritidis* in a dilution of 1:640. The organism was then isolated from the urine and from the stools. Although rose spots appeared on the abdomen blood cultures remained sterile.

On July 27 sulfaguanidine therapy was instituted. Stool and urine cultures soon became negative, and the tempera-

ture returned to normal. X-ray films taken on August 2 showed a destructive process in the body of the fourth lumbar vertebra. The patient remained afebrile but because of pain he was immobilized in a plaster shell and evacuated to the United States. The subsequent course of the illness is not known.

CASE 6. This patient was in the Buna-Sanananda area from late November to late December, 1942. In the latter month he had two mild attacks of diarrhea and on December 24 a bout of malaria with a positive smear which responded promptly to specific therapy. He had two further attacks of malaria one in January and one in March, 1943, both of which responded satisfactorily to treatment.

On April 8 while on duty in Australia he developed pain and swelling in the left testicle. He was afebrile, and there were no systemic symptoms. He was admitted to a hospital, where he received sulfadiazine and applications of ice to the testicle. The pain and swelling gradually subsided, and he was returned to duty. Two days later the same symptoms recurred.

On admission to a general hospital on May 7 he was afebrile. Physical examination revealed no abnormalities other than a tender moderately enlarged left testis, with some thickening of the cord. Routine laboratory examinations were negative. The white-cell count was 9000.

On May 13 an orchidectomy was performed. The testis was found to be distended by a large abscess filled with thin gray fluid. *S. enteritidis* was isolated in pure culture from the exudate. Blood and urine cultures were then taken and proved sterile, but on several occasions the stools were found to contain the same organism. Sulfaguanidine therapy was accordingly administered and was followed by the disappearance of the organism from the stool. Complete healing of the surgical wound occurred and the patient was discharged to duty on October 6.

BACTERIOLOGY

Salmonella organisms grow readily on ordinary bacteriologic mediums, and in most cases a tentative identification can be made within a few days by

TABLE 1 Sources of *S. enteritidis* and Maximum Serum Agglutination Titers

Case No.	SOURCE				MAXIMUM TITERS
	BLOOD CULTURE	URINE CULTURE	STOOL CULTURE	ABSCESS CULTURE	
1	Positive	Negative	Positive	Positive	1:2560
2	Negative	Negative	Negative	Positive	1:320
3	Negative	Negative	Negative	Positive	1:2560
4	Negative	Positive	Positive	Positive	1:640
5	Negative	Positive	Positive	Positive	1:640
6	Negative	Negative	Positive	Positive	1:640

fermentation reactions and simple group-agglutination tests.* Definitive identification within the group, which depends on minor variations in antigenic structure, should be delegated to laboratories specifically equipped for such work†

Table 1 presents the various sources from which the organism was recovered in each case. It should be realized that cultures were rarely taken during

*The biochemical reactions were constant in all cases. The organisms promptly fermented the 4-11 ring sugars with the production of acid and gas; dextran, maltose, mannitol, xylose, arabinose, rhamnose, and D-sorbitol. D-glucose was fermented only after four or five days. Lactose, saccharose, inositol, and inulin were not fermented. The organisms produced large amounts of hydrogen sulfide. It did not produce indole or H₂S by gelatin.

†We are indebted to Dr. Erich Seligmann of the Department of Bacteriology, Beth Israel Hospital, New York City, who determined the antigenic structure of the organism.

periods of the infection in which positive results were likeliest to occur — that is, they were obtained for the most part late in the course of the disease

In a case of vertebral abscess (Case 2) the diagnosis was based only on the presence of a high agglutinin titer in the serum. One might question whether this case should have been included, but because the clinical course was similar to that in Case 1, we consider inclusion justified, although the organism was not isolated.

The antigen for the agglutination tests was prepared from freshly isolated strains suspended in 0.5 per cent phenol in physiologic saline solution. In each case the serum gave a flocculent ("flagellar") type of agglutination. As would be expected by reason of common somatic antigens, O strains of typhoid bacilli were also agglutinated by these serums in high dilution.

EPIDEMIOLOGY

Data concerning the number of troops affected in this outbreak of *S. enteritidis* infection are unobtainable, because in most cases the symptoms were probably mild and because, in the exigencies of bitter jungle fighting, many men failed to report diarrheas and even fevers that were not incapacitating, nor were adequate diagnostic facilities available at the front.

Although the evidence is not conclusive, it seems likely that the majority of infections were contracted from the same source and at about the same time. All the cases presented above did not occur in the same company, but they occurred in the small Buna-Sanananda area of the jungle for varying periods during December, 1942, and January, 1943. For three days — that is, from December 25 to 27 — 5 of the 6 patients were there simultaneously. It seems reasonable to assume that infection took place at or about that time. To our knowledge no subsequent cases of infection with *S. enteritidis* occurred elsewhere as the campaign progressed in New Guinea.

Nor have we any definite evidence regarding the source of the outbreak. It appears unlikely that infection occurred from the ingestion of food products from infected animals — the usual source of *Salmonella* outbreaks — since the diet of the troops was limited entirely to C rations, which consisted of dried and tinned food processed in the United States. Infection may have originated from a carrier of the organism among Allied or enemy troops or from one of the native bearers. Rats have been known to harbor the organism,¹² and there were many rats in the area.

The infection was probably transmitted through contaminated drinking water. Water was obtained from the corpse-strewn, rat-infested swamps in which the troops fought. Boiling was rarely possible, and individual chlorination was at best haphazard. The epidemic may have been fly-borne, for flies

were plentiful. Excreta were usually deposited where circumstances permitted.

DISCUSSION

In a recent review of *Salmonella* infections, Bornstein¹³ describes the following clinical syndromes resulting from human infection with these organisms:

Salmonella gastroenteritis The essential features are the abrupt onset of vomiting and nonbloody diarrhea eight to thirty-six hours after the ingestion of contaminated food or water. There may be slight fever for a few days, but there is usually prompt recovery.

Salmonella fever A typhoid-like course, leukopenia, splenomegaly, abdominal pain and occasionally vomiting and diarrhea occur. The disease is generally milder and less typical than that caused by *E. typhosa*. Blood cultures are positive early in the disease.

Salmonella septicemia Impressive invasion of the blood stream is usually present from the onset of a high remittent fever. Localization of the infection through hematogenous dissemination is likely and spares few structures. Bronchopneumonia, osteomyelitis, meningitis, pyarthrosis and endocarditis are not rare.

Bornstein stresses the point that on occasion any *Salmonella* may produce one of the syndromes listed above. The clinical course in the cases reported above was far different from that in the simple gastroenteritis usually produced by this organism. In 5 cases there was prolonged fever simulating that seen in infections caused by *E. typhosa*, an organism with which *S. enteritidis* shares common somatic antigens. In all cases there were prominent suppurative features such as are occasionally seen in infections with Group C *Salmonella* organisms, particularly *S. choleraesuis*.¹⁴

Lack of familiarity with the natural history of *Salmonella septicemia* and its sequelae led to delay in diagnosis in most of the cases. In none was the diagnosis made on admission to the hospital. In retrospect, however, survey of the clinical features brings out certain distinctive characteristics.

The 6 patients may be separated into two groups: those who developed a sustained nonmalarial fever and evidence of blood-stream invasion while in the combat area, where opportunity for this infection was present, and those who had no characteristic symptoms of *Salmonella* infection until suppurative lesions manifested themselves three to six months after the patient had left the combat area. This prolonged period of asymptomatic infection was the striking feature in the latter group of cases, but even in the first group the sometimes indolent character and always insidious development of suppurative lesions were noteworthy. In Case 1 five weeks had elapsed and the initial fever had abated before the appearance of subcutaneous swelling overlying

a costal cartilage indicated the presenting abscess. The patient in Case 2 had been convalescent for four weeks after nine weeks of fever, pneumonitis and urinary-tract infection when he developed excruciating pain in the back and a recurrence of fever that lasted for five weeks. X-ray examination ultimately revealed destructive changes in two lumbar vertebrae. Case 3 illustrates an earlier appearance of symptoms referable to localized infection, but the abscess was long in developing to a conspicuous degree. This patient noted a tender area on the anterior aspect of the chest wall during his initial twelve-day fever. It was not until three months later that a suppurating mass appeared in the area and gave the first opportunity for correct diagnosis.

Cases 4 and 5, in the second group, closely resembled Case 2 except that the patients did not have a sufficiently prolonged initial fever to warrant hospitalization. As in Case 2 the subsequent onset of symptoms of localized Salmonella infection was accompanied by fever. In Case 4 the association of the fever with a normal white-cell count and pain in the left upper quadrant and shoulder led to a tentative diagnosis of malaria despite the absence of parasites in the blood smears. Antimalarial treatment was unavailing. It was not until an abscess presented and was drained that the diagnosis of Salmonella infection was established and its tendency to manifest itself in localized suppuration was recognized. Again, in Case 5, the backache was at first erroneously attributed to malaria without due consideration for the severity of the pain and with delay in obtaining x-ray evidence of osteomyelitis of the lumbar spine. Case 6 was unique in that the slow development of a testicular abscess was not associated with fever.

The propensity of the patients to develop recurrences of fever is noteworthy. Fever usually reappeared in association with the suppurative lesions. In Case 1 the blood culture was positive for *S. enteritidis* during the relapse. The second febrile episode in Cases 4 and 5 may well have represented recurrences of bacteremia also.

The likelihood of genitourinary-tract infection in the early stage of bacteremia is borne out by the presence of epididymitis in Cases 1 and 2, positive urine cultures for the organism in Cases 4 and 5 and the development of a testicular abscess in Case 6.

The localization of infection in the costal cartilage in 2 cases bears an interesting similarity to the behavior of other Salmonella infections. Ssokoloff¹⁵ described 10 cases in which *S. choleraesuis* produced a costal chondritis. The cases occurred during the Russian typhoid-paratyphoid epidemic of 1919-1923

and were generally associated with a "paratyphoid relapse."

Various sulfonamides have been reported of value in the treatment of Salmonella infections. No definite conclusions, however, can be drawn regarding the efficacy of sulfonamide therapy in the cases presented above. Different drugs were administered in varying dosages for arbitrary periods during the infections. In only 1 case (Case 2) did a sulfonamide appear to exert no beneficial effect whatever.

In 4 cases a stool-carrier state developed. In each case the organism disappeared from the stool following sulfaguanidine in doses varying from 3 gm every four hours to 3 gm every eight hours, continued for several weeks. But this apparent success must be interpreted in light of the observation that convalescent Salmonella carrier states usually terminate spontaneously in a matter of weeks.¹²

SUMMARY

An outbreak of infection caused by *Salmonella enteritidis* among troops in the Papuan campaign in New Guinea is reported.

In some cases the disease progressed far beyond the acute gastroenteritis usually associated with infections caused by this organism. Six cases seen in a general hospital with late manifestations of the infection are presented. In 5 the infection was associated with a condition similar to typhoid fever. All cases eventually developed focal suppuration.

The cases serve to illustrate the recent concept of the protean nature of Salmonella infections.

FAMILIAL HEMORRHAGIC TELANGIECTASIA*

With a Note on the Use of Oxidized Cellulose Gauze as a Hemostatic Agent in Epistaxis

HOWARD P. KENNEDY, M.D.†

SPRINGFIELD, MASSACHUSETTS

THE occurrence of epistaxis in association with developmental anomalies of the blood vessels was first mentioned by Sutton¹ in 1864. Babington² described hereditary epistaxis in 1865. Thirty-one years later Rendu³ reported the same condition in a patient with cutaneous angiomas. The classic monograph of Sir William Osler⁴ in 1901 on a form of familial recurrent epistaxis associated with multiple telangiectases of the skin and mucous membranes did much to establish the syndrome as a clinical entity. Weber⁵ presented an account of another case of this rare disorder in 1907. Today, the Rendu-Osler-Weber disease, often referred to as Osler's disease, is known as familial hemorrhagic telangiectasia.

Although there is reason to believe that this disease occurs much more frequently than the number of reported cases indicates, about 500 patients in more than a hundred families have been described in the literature up to the present time. The disease occurs equally in both sexes, and is transmitted as a simple dominant by both men and women. Wintrobe⁶ states that families of the following stocks are affected in the order indicated: Anglo-German, Latin, Scandinavian and Jewish.

The cause of this morbid derangement of the capillaries is unknown, but the condition has been placed in the nondescript group of disorders often referred to as exhibiting degenerative stigmas. Teahan⁷ has traced the disease in six generations of one family. Since severe bleeding does not begin until the fourth or fifth decade, it has been thought that an endocrine factor at least aggravates the bleeding tendency. The results of estrogenic therapy have not supported this belief. Arteriosclerosis and aging processes may contribute to the hemorrhagic proclivity, but even here the evidence is not too convincing. It is interesting to note that Singer and Wolfson⁸ found increased capillary fragility as evidenced by a positive tourniquet test in their study. These authors link the disorder to hereditary familial vascular purpura. Wells⁹ reported 2 cases of the disease with a prolonged bleeding time, in one of which the patient showed increased capillary fragility. As a result of these findings Wells believes that the disease also overlaps von Willebrand's¹⁰ pseudohemophilia. Familial hemorrhagic telangiectasia, hereditary familial vascular purpura, and pseudohemophilia, together with familial epistaxis

without telangiectasia, may stem from a common hereditary vascular dysplasia. With the present unsatisfactory classification of these diseases in mind, these disorders are reviewed in the light of newer physiologic and anatomic findings.

The telangiectases have been known to occur in almost every organ of the body. On the skin they appear as small violaceous spots 0.1 to 3.0 mm in diameter. Spider telangiectases are sometimes visible on the face, and large vascular nevi covering the nose have been reported.¹¹ On the nasal mucosa the small reddish purple spots dot the septum and floor of the cavity. They may be seen on the tongue and oral mucosa. Lesions have been reported in the stomach on gastroscopic examination¹² and have been confused with ulcer, with which they may be associated. Telangiectasia of the lungs may be a more frequent cause of pulmonary hemorrhage than is ordinarily thought. Hematuria has been described by continental writers,¹³ and it is well to inquire carefully about familial bleeding in cases of essential hematuria in patients over forty years of age. The lesions of the skin are not always permanent as has been stated in the literature. In the case reported below, the telangiectases were often absent at various examinations. Hepatomegaly, splenomegaly and increasing intolerance to blood transfusions of Type O have been reported by Fitz-Hugh.¹⁴ The blood picture in cases of familial hemorrhagic telangiectasia is normal, except for the posthemorrhagic anemia that results from the repeated bleeding. The microscopical features of the disorder have often been commented on.^{15, 16} The terminal vessels, capillaries and venules are dilated and thinned. Covered by a scanty layer of epithelium, these thinned and dilated vessels are either easily traumatized or else ruptured by some unknown intrinsic factor, with resultant bleeding. It can be seen, then, that the disease is inherently a capillary disorder. Hemorrhage is usually associated with lesions of the nasal mucosa.

The typical telangiectases may be found early in life, but they seldom cause serious hemorrhage until the patient reaches the fourth decade. Epistaxis then becomes increasingly troublesome and serious as age advances. Many patients have the lesions but not the bleeding tendency. This, together with atavism,¹⁷ may explain, to some extent, the absence of the disease in some generations of a family. Repeated hemorrhage—usually epistaxis—in either sex at about the fourth decade or after, a positive

*From the Springfield Hospital.

†Physician, Out Patient Department, Springfield Hospital.

family history of bleeding and the presence of telangiectases on the skin and mucous membranes, particularly the nasal mucosa, suggest the diagnosis of familial hemorrhagic telangiectasia. The typical blood dyscrasias are usually excluded by the presence of normal blood physiology.

The most serious complication of the disease is fatal hemorrhage. The mortality from hemorrhage per se is given as 3 to 6 per cent by various authors. Most of the patients with familial hemorrhagic telangiectasia harbor a secondary anemia from the repeated blood loss. It is surprising how well they adapt themselves to this posthemorrhagic state.

Some students of the disease think that snake venom helps to control the bleeding. Styptics and thromboplastin are of temporary value when applied locally in conjunction with pressure or a nasal pack. I have found a latex finger cot tied around the end of a catheter and inflated, to be a useful aid in maintaining hemostasis preparatory to the insertion of a nasal tampon. Radiation may induce a remission of one to three years, but it is reported to have caused destruction of the septum. No physician who has observed these patients after repeated and thorough cauterization can conscientiously say that he has been tremendously im-

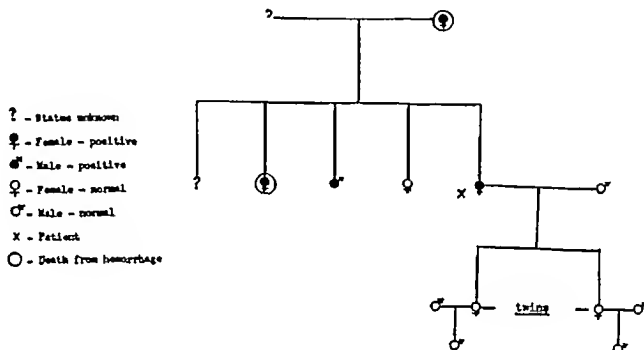

FIGURE 1

Infarction of the lungs is apt to occur when bed rest is abused following hemorrhage. The alterations of the blood due to the anemia may be a contributing factor to the phlebothrombosis. It is conceivable that the anemia and prolonged hemorrhage in an arteriosclerotic heart may initiate an acute coronary insufficiency.

The prognosis, in the absence of complications and provided hemorrhage can be controlled, is good so far as life is concerned. The severe and at times intractable hemorrhage, together with the anemia, often either makes semi-invalids of these patients or causes them to live restricted lives. Because of the repeated epistaxis, they pay numerous visits to the emergency wards of hospitals.

The treatment of familial hemorrhagic telangiectasia consists essentially of the control of epistaxis of varying degrees of severity. The multitude of agents and measures used in arresting the hemorrhage attests to failure to find a satisfactory method of managing the victims of this disorder. According to recent reports, one of the newer therapeutic agents for decreasing capillary fragility, although not a specific, may be of some help in controlling the hemorrhagic tendency.^{18, 19} Endocrine preparations, as mentioned above, have given indifferent

results. A measure of relief may be obtained by sclerosing of the vessels, but this requires a certain amount of skill that is outside the province of the average general practitioner. The fairly constant formation of new telangiectatic areas nullifies the effect of painstaking cauterization or sclerosis. Sooner or later one must rely on a tight vaseline-soaked gauze nasal pack. The patient complains of discomfort when this is inserted daily or every other day for weeks at a time, as is often necessary. The foul odor is obnoxious to the patient, to other members of the household and to the physician alike.

The case reported below illustrates the successful management of familial hemorrhagic telangiectasia and intractable epistaxis with a new hemostatic material, — oxidized cellulose gauze, — as described by Frantz and Lattes,²⁰ whose excellent article describes the preparation, action and uses of this latest addition to the list of hemostatic agents.

CASE REPORT

G. C., a 60-year-old housewife of Scottish English extraction, was admitted to the hospital because of severe nose bleeds. Since childhood she had had epistaxis, which had always been controlled by ice and light nasal packings until about 5 years before admission, when the hemorrhages occurred

more frequently and became severer. She had had many hospital admissions for arrest of the bleeding. Four years before admission she had been treated with radium. During the next 2 or 3 years the bleeding was less severe and occurred at longer intervals. For the greater part of the previous 10 months the patient had had a firm nasal packing of vaseline gauze inserted in the right nostril. The packing was removed and reinserted daily or on alternate days. On some occasions during this period she was able to go about her duties for several days without the packing. Usually, a sudden severe nosebleed, initiated by a cough or sneeze during an attack of asthma, necessitated emergency treatment and a return to the nasal pack. During such episodes it was not unusual for her to lose 400 to 800 cc of blood. At times she became so weak from hemorrhage that she was confined to bed for varying periods. While a patient at another hospital, she developed phlebotrombosis of both lower extremities and an infarct of the left lower lung. Bilateral superficial femoral-vein ligation was done, and she was discharged. She continued to have minor episodes of infarction after her return home.

The mother had died at the age of 52 of hemorrhage from the nose. A sister had died at 65 in a posthemorrhagic state following severe nasal bleeding. A brother, 63 years of age, had heart disease, and had had many hospital admissions, for nosebleeds. Three sons of this brother had reached adulthood without apparent bleeding. Another sister had died at the age of 21 of pneumonia following measles. A sister with hypertensive heart disease was living at the age of 68 and had no symptoms or signs of capillary hemorrhage. Each of twin daughters had a son, neither the daughters nor their sons showed telangiectases or any bleeding tendency.

The patient had had measles, mumps and whooping cough during childhood and for the past 20 years had had moderate to severe attacks of bronchial asthma. She had had three operations for frontal sinusitis about 30 years previously. At the age of 20, a bilateral oophorectomy had been performed. There were no symptoms referable to the gastrointestinal tract. The patient complained of slight exertional dyspnea and occasional attacks of pain across the upper chest. She had no genitourinary complaints and slept well when free from asthma and epistaxis. Menstruation had ceased following the operation 40 years previously.

Physical examination showed an obese woman who was bleeding rather profusely from the right nares through a firmly inserted nasal pack. Examination of the pharynx revealed postnasal hemorrhage. The nasal packing was removed, and a tight vaseline-soaked gauze tampon was inserted well into the cavity. The bleeding ceased, and the patient was given sedation and admitted to the hospital. The pulse was 92, and the blood pressure 60/50.

Examination of the blood disclosed a red-cell count of 3,700,000, with a hemoglobin of 69 per cent (9.9 gm Sahli), and a white-cell count of 6400, with 43 per cent neutrophils, 50 per cent lymphocytes, 1 per cent eosinophils and 6 per cent monocytes. The clotting time was 4 minutes, and the bleeding time 1 minute. The platelet count was 290,000. The prothrombin time of the patient and a control was 23 seconds. The hematocrit was 34, the specific gravity of whole blood 1.045, and the mean cell diameter of the red cells 7.7 cubic microns. There was beginning clot retraction in 15 minutes, with completion in 3 hours. The resistance of the red cells to hypotonic saline solution was normal. The patient was Type I AB, and Rh+. There was no indication of increased capillary fragility by the tourniquet test. A blood Hinton test was negative. The urine was essentially normal except that the sediment contained many white cells in an uncatheterized specimen. A chest film showed slight blunting of the right costophrenic angle indicative of an old pleurisy and some lateral protrusion of the lower left contour of the heart. An electrocardiogram showed small Q waves in Leads 1 and 2 and a low T wave in Lead 1. It was interpreted as being suggestive of myocardial damage.

Examination of the nose on the next day was unsatisfactory because of oozing, but a nose and throat consultant reported that the mucosa showed many telangiectatic areas and a moderate degree of atrophy. The telangiectases were more numerous and more marked on the right. A tiny, reddish-purple area was present on the tip of the tongue. A second lesion was seen on the ball of the index finger of the left hand. Several areas of telangiectases over the trunk, arms and

thighs, seen on previous examinations, had disappeared. On the fifth hospital day the blood pressure was 120/90 and the pulse 80.

The nasal pack was removed daily and reinserted. On the 7th hospital day it was not replaced, in spite of slight oozing. Since the patient had had two severe transfusion reactions during a previous admission to another hospital and because it was feared that an increase in blood volume might initiate hemorrhage, she was discharged 21 days after admission with a red-cell count of 3,300,000 and a hemoglobin of 62 per cent (8.9 gm Sahli).

Twenty-four days later she was readmitted with severe nasal hemorrhage. It was necessary to insert firm anterior and posterior nasal packs in the right nostril, as well as a light anterior pack in the left nostril. The patient was discharged on the following day with an anterior nasal pack of vaseline-soaked gauze. The red-cell count was 3,700,000, and the hemoglobin 58 per cent (8.3 gm Sahli). The hemorrhage was well controlled. Ten days later she was seen in the Emergency Room with severe epistaxis. At that time a firm tampon was inserted in the right nostril. This was changed on alternate days in her home.

The fourth admission for severe epistaxis took place 18 days following the last treatment in the Emergency Room. Oozing from the right nares had been continuous for 5 or 6 days in spite of a firmly inserted nasal tampon. The red-cell count was 3,700,000, and the hemoglobin 64 per cent (9.1 gm Sahli). The nasal packing was removed and reinserted. On the following day it was again removed. Bleeding had ceased, and it was not replaced. On the 3rd hospital day blood suddenly gushed from the right nostril following a cough, and the hemorrhage was controlled with difficulty. Several inches of oxidized cellulose gauze,* which had been obtained from the manufacturer at the suggestion of Dr. Roderick Macaulay, was inserted into the right nostril after the method of Houser.²¹ After a lapse of 2 or 3 minutes the hemorrhage ceased. Two days later the resulting brittle material had been absorbed, and the bleeding began again. The nose was repacked, and the bleeding was almost immediately arrested. More of the material was used at this packing than previously. On the next day the gauze became granular and, within 24 hours, began to drop postnasally as tiny bits of a harmless gelatinous substance. Absorption and elimination were fairly complete in 7 days, and hemorrhage ensued. Prompt packing caused the bleeding to cease at once. The hemostatic material became loose in the nasal cavity and was removed 6 days after insertion. Inasmuch as epistaxis did not ensue, the pack was not reinserted. Eight days elapsed with only occasional episodes of minor oozing. This was readily controlled by the patient, but often stopped spontaneously. The patient was placed on 20 mg of rutin 3 times a day, the immediate members of her family were given instructions on the insertion of the oxidized cellulose gauze, and she was discharged on the 26th hospital day. On subsequent office visits the amount of rutin was increased to 40 mg 3 times a day. Because of nausea, it was necessary to reduce this dosage to a total daily maintenance dose of 100 mg. The hemorrhages, now easily controlled by oxidized cellulose gauze, have become less frequent and less severe since the institution of the rutin therapy. At present the patient is able to carry on all her normal activities, including household duties, with no difficulty.

SUMMARY

The essential features of familial hemorrhagic telangiectasia (Rendu-Osler-Weber disease) are reviewed. The disease may be more closely related to other familial, hereditary hemorrhagic disorders than was formerly believed.

A case with intractable epistaxis is reported and discussed from the viewpoint of management with a new hemostatic product. Oxidized cellulose gauze should prove a useful addition to the therapeutic armamentarium for the control of epistaxis because

*The material used was a 12-cm Hemo-Pak, manufactured by Johnson and Johnson, New Brunswick, New Jersey.

it is easily inserted, its hemostatic efficiency is high, it causes no discomfort to the patient, it is free from objectionable odor, and it is practically completely absorbed

RENAL INJURY FOLLOWING EXPOSURE TO CARBON TETRACHLORIDE*

Report of a Case

MARSHALL CLINTON, JR., M.D.†

BOSTON

MOST physicians associate carbon tetrachloride poisoning with serious liver damage and jaundice. This is not surprising, since knowledge of this substance stems from medical-school teaching, in which carbon tetrachloride was cited as an etiologic agent in toxic cirrhosis or acute atrophy of the liver and emphasis was placed on the risk of liver damage following the improper use of carbon tetrachloride as a vermifuge. The association of carbon tetrachloride with liver injury is also due in part to familiarity with its use as a hepatotoxic agent in animal experiments.¹⁻³ It is not generally recognized, however, that the inhalation of carbon tetrachloride by man frequently results in a clinical picture in which renal and pulmonary injury predominate and liver injury is not evident, although numerous authors have described such cases in more or less detail.⁴⁻¹⁰ It appears that the syndrome of renal failure, accompanied by hypertension and severe azotemia induced by heavy exposure to carbon tetrachloride vapor, deserves additional emphasis in the general literature so that such cases may be recognized promptly and handled properly. The following case is therefore reported in detail.

G L, a 51 year-old Italian laborer employed in a large modern chemical plant in the Boston Metropolitan Area, was admitted to the hospital on June 14 1946. He had been in good health all his life and was known to have had a normal blood pressure in 1945. According to his neighbors he drank wine fairly steadily but seldom became drunk. On May 28 he and six other laborers were assigned the job of cleaning

thick grease from the gears of a large mill prior to its being dismantled. They were at first given open buckets of naphtha and cloths with which to accomplish this task, but at 2:00 p.m. on May 29 the naphtha was replaced by carbon tetrachloride after an explosion meter test indicated the presence of an explosive concentration of naphtha about them. The seven men then worked with open buckets of carbon tetrachloride in which they soaked their rags to dissolve the thick grease. The work was carried on in a large, open room with 31 044 square feet of floor space and with adequate general but no local ventilation. The men were instructed to leave the vicinity of the work and get some fresh air for about 5 minutes every 1½ hour. Six of the men apparently did so to smoke. The patient, a nonsmoker and an unusually conscientious worker, did not take these rest periods but continued to work steadily. All seven men worked at this job from 2:00 to 4:30 p.m. on May 29. The plant was closed the next day but on May 31 the same group worked from 8:00 a.m. to 4:30 p.m., except for a laborer who had been removed from the job about noon because he complained of "stomach ache and biliary vision." (This man's complaints cleared up on transfer to outdoor work and no subsequent illness developed.) On the following day the remaining six laborers again went to work with their buckets of carbon tetrachloride. The patient was removed from the job and assigned outdoor work about 2:00 p.m. after he had complained of dizziness and nausea. The remaining five men continued on the job which they completed without incident or illness toward the end of the following week.

The patient felt worse instead of better after his transfer to outdoor work, and was forced to leave the plant early because of nausea and abdominal discomfort. At home that evening the nausea increased and was accompanied by frequent emesis. He complained of generalized crampy abdominal pain and severe occipital headache. Several chills occurred, although no fever was noticed by his wife. That night the patient developed a dry, hacking nonproductive cough accompanied by pain in the lower chest and epigastrium. These complaints continued during the next 2 weeks during which there were frequent bouts of vertigo, chills, extreme anorexia and nausea as well as intermittent severe occipital headache. Vomiting occurred frequently and on one occasion bright red blood was noted in the vomitus. Considerable abdominal distention developed although the bowels moved daily, the

*From the Medical Clinic, Peter Bent Brigham Hospital, and the Department of Industrial Hygiene, Harvard School of Public Health.
†Associate in Industrial Hygiene, Harvard School of Public Health.
Junior associate in medicine, Peter Bent Brigham Hospital.

stools being normal in color and consistence. On several occasions there were complaints of intermittent dimming of vision, described as being "like a cloud over the sun." Blood clots were expelled from the nose frequently, although no frank nosebleeds were noted. At no time were there any clinical signs of icterus or any evidence of bile in the urine.

The cause of the illness apparently was not clear during this period, although the exposure to carbon tetrachloride had been brought to the attention of the family physician by the plant nurse. Diagnostic x-ray examinations, including a gall-bladder series, gastrointestinal series and barium enema, were reported to be negative, although a small esophageal diverticulum was noted at the level of the seventh rib. The

remained restless and somewhat confused, and the nausea and headache continued during the first 3 hospital days. On the 4th day the patient began to feel better. The symptoms gradually lessened, and his condition slowly improved throughout the remainder of the hospital stay. On the 5th day, however, the temperature rose to 102°F and the cough increased, although the lungs remained clear clinically. Intra-muscular injections of 30,000 units of penicillin every 2 hours were administered from the 5th through 9th hospital day. The administration of penicillin was accompanied by a rapid fall in temperature to normal, disappearance of the cough and clearing of the x-ray picture. The blood pressure, which had been markedly elevated on admission, fell slowly to al-

patient was referred to the hospital when his condition was becoming progressively worse, with increasing anorexia, vomiting, abdominal discomfort and lethargy.

Physical examination revealed a lethargic, somnolent, acutely ill patient. The breath was foul. No jaundice, cyanosis or petechiae were noted. The conjunctivae were pale, and the mucous membranes of the mouth were studded with purpuric spots. Examination of the chest revealed diminished expansion, but the lungs were clear throughout. The heart was slightly enlarged to the left, and the rate was regular and rapid, with a Grade I systolic murmur at the apex. The abdomen was soft and nontender. No organs or masses were palpable, and liver dullness was normal in extent. There was no evidence of free peritoneal fluid. The remainder of the physical examination was not remarkable.

The temperature was 98°F, the pulse 90, and the respirations 36. The blood pressure was 210/100.

Examination of the blood at the time of admission disclosed a hemoglobin of 15.1 gm and a white-cell count of 11,500, with a fairly normal differential. The platelets appeared normal. The urine had a specific gravity of 1.010 and gave a + test for protein, and the sediment contained 40 to 50 red cells per high-power field. A rare cellular cast was noted. Blood chemical studies revealed the presence of a fairly severe nitrogen retention and moderate acidosis. The total protein, calcium, phosphorus and alkaline phosphatase were normal.

X-ray examination of the chest on the day after admission revealed a diffuse granular increase in the markings in both lung bases, most marked on the left, where there was a small amount of fluid in the costophrenic angle. These findings were interpreted as suggesting a resolving pneumonia at the bases. The x-ray film also disclosed slight cardiac enlargement. An electrocardiogram was normal.

The patient was given intravenous infusions of glucose, physiologic saline solution and sodium bicarbonate, as well as 10 gm of methionine by mouth, and 5 cc. of crude liver extract intramuscularly each day. Lumbar puncture on the 2nd hospital day revealed no abnormalities. The patient re-

most normal levels at the time of discharge. The blood urea nitrogen, blood pressure and other blood chemical changes during the hospital stay are presented in Table 1.

While the patient was in the hospital, special tests of liver and kidney function were performed. The thymol turbidity was never elevated above normal, although it dropped from a level of 5 Maclagan units¹¹ following admission to 1 unit at the time of discharge. The bromsulfalein test indicated a persistent increase in dye retention, but no elevation in serum bilirubin was present at any time. The urea clearance and phenolsulfonephthalein excretion were impaired throughout the hospital stay.

The patient was discharged from the hospital 20 days after admission. At that time he appeared well but still complained of frequent occipital headaches and generalized weakness. Six weeks after the exposure to carbon tetrachloride, he felt perfectly well and was able to return to work. At that time physical examination was not remarkable, and the liver and spleen were not palpable. The blood pressure was 136/82, and the nonprotein nitrogen 33 mg per 100 cc.

This case illustrates several points in connection with poisoning following relatively brief exposure to carbon tetrachloride that deserve emphasis. The absence of any fire or explosion hazard has endowed carbon tetrachloride with a reputation as a safe solvent for general use that it does not deserve. In this case, carbon tetrachloride was substituted for naphtha to eliminate the explosion hazard accompanying the use of the inflammable solvent. It should have been evident that a toxic concentration of carbon tetrachloride would be encountered, since the explosion-meter test disclosed an explosive con-

centration of naphtha (this would be at least 1 per cent), and carbon tetrachloride is even more volatile. It is surprising that all the workers were not affected, for serious or even fatal poisoning may follow exposure to 0.1 to 0.5 per cent carbon tetrachloride.¹² There was undoubtedly considerable variation in the concentration actually breathed, however, the explosive naphtha concentrations were encountered near the buckets rather than at head level. Unfortunately, no carbon tetrachloride concentrations were determined.

Marked variation in susceptibility to poisoning by carbon tetrachloride has previously been noted.¹²⁻¹⁵ It is interesting that only two men of the seven exposed were affected and that only one was made seriously ill. It is quite possible, however, that careful examination and testing of the remaining men would have disclosed some evidences of kidney or liver injury.

It is impossible to state whether the therapy that the patient received after reaching the hospital had any pronounced effect on the course of the disease despite the diuresis and fall in blood urea nitrogen observed, since diuresis may be expected at about this time in the natural course of the disease. It appears probable, however, that the administration of fluids and electrolytes was helpful in promoting a return of kidney function. The effect of methionine on the clinical course is not clear, its action in protecting the livers of protein-depleted dogs from injury from chlorinated hydrocarbons has been amply demonstrated.¹⁶⁻¹⁸ Shaffer, Carpenter and Moses⁴ have shown, however, that methionine is ineffective in preventing or correcting liver damage from carbon tetrachloride in dogs with an adequate protein reserve. The fact that the patient had eaten relatively little for the two weeks prior to admission made it appear desirable to give him an adequate protein intake. It was considered necessary, however, to maintain the protein intake at a relatively low level, adequate calories being supplied in the form of carbohydrate, to avoid an excessive accumulation of nitrogenous waste products in the body, and methionine was supplied in an effort to mitigate the undesirable effects on the already damaged liver of further protein depletion. Therapy in this case was directed primarily at the kidneys, since regeneration of the liver proceeds rapidly following acute poisoning by carbon tetrachloride and since liver damage in this case was not at any time sufficiently severe to cause clinical icterus. Conservative measures were adequate.

The multiplicity of action of carbon tetrachloride is well illustrated by this case. Definite evidences of pulmonary irritation and impaired liver function were noted, and the history suggested that gastrointestinal involvement was present during the first

week of the illness. Reports in the literature indicate that carbon tetrachloride poisoning is characterized by pulmonary involvement⁶ or acute abdominal symptoms,¹⁶ as well as the more frequent renal or liver injury. Recently, carbon tetrachloride has been reported to induce the development of duodenal ulcer.¹⁷

SUMMARY

The generally accepted but erroneous belief that acute carbon tetrachloride poisoning is usually associated with severe liver injury may lead to failure to establish a correct diagnosis in cases of carbon tetrachloride poisoning resulting from inhalation of its vapors.

A case of severe renal injury without clinical evidence of liver injury following brief but intense exposure to carbon tetrachloride vapor is presented in detail.

The clinical picture in this case was dominated by anorexia, lethargy, hypertension, azotemia and urinary findings suggestive of nephritis. Complete recovery, with a return of the blood pressure to normal, and disappearance of evidences of renal disease took place under conservative therapy.

The possibility that this syndrome occurs frequently following the inhalation of carbon tetrachloride is emphasized.

THE DETECTION OF TUBERCLE BACILLI BY FLUORESCENCE MICROSCOPY

LEON LEVINSON, M D,* AND R LEONARD WHITE, M D†

BOSTON

THE method of fluorescent staining for the demonstration of tubercle bacilli in smears proposed in 1937 by Hagemann¹ offered a promising simplification of the rather cumbersome Ziehl-Neelsen technic. Many in this country have tried the procedure and have not been impressed with the results.² The objections are in some cases due to insufficient trial and in others to inadequate equipment. Better methods have now been developed, and it is the purpose of this paper to outline the technic and equipment and the results obtained therewith.

The tubercle bacillus does not fluoresce of its own accord but can be made to do so by staining with a fluorescent dye. Auramine O, readily available from several supply houses, was used in the studies described below. A saturated aqueous solution of this dye is filtered to remove the surplus undissolved particles. The filtrate is unstable but will retain its staining power as long as two weeks if kept in the refrigerator. Thinly spread, heat-fixed smears on new glass slides are stained for two minutes with this auramine solution at room temperature without the troublesome steaming required by the Ziehl-Neelsen method. The slides are then washed in water, decolorized with acid alcohol and again washed with water. They are then counterstained with a 1:1000 aqueous solution of potassium permanganate for thirty seconds, as recommended by Lee,³ washed with water and allowed to dry in the air. The whole procedure requires only about three and a half minutes.

Light sources originally supplied for the purpose are not adequate. The present studies were done with a home-made lamp and filter described by Graham.^{4, 5} The materials cost less than ten dollars. The essential parts are a 500-watt motion-picture projector bulb in a sheet metal housing, which also holds two 7.5-cm. double condensing lenses. It is necessary to delete from the lamp beam all but the blue light, this may be accomplished by the use of a liquid filter made as follows. An excess of ammonium hydroxide is added to a saturated aqueous solution of copper sulfate, this is placed in a rectangular museum jar and is diluted with water until the correct shade is obtained to give the results described below.

The wave length of the exciting and emitted light is further narrowed by placing in the ocular lens of the microscope a yellow glass filter equivalent to a Wratten K-2. This and the proper dilution of

the aqueous filter will give a Nile-green background. This background for the microscopical field is chosen in preference to the black background usually advised. Against a green color, nonfluorescent elements on the slide are readily seen, and the focus can be maintained throughout the search for fluorescent particles. The green color minimizes eyestrain, to which some workers have objected. Another objection has been that a dark room is needed for examination of fluorescent-stained smears. When the green background is used it is only necessary to reduce the light in the examining room somewhat—for example, by drawing the shades nearest the microscope. We have found this most suitable for general use. Any standard monocular microscope with a 10x ocular and with 10x and 43x objectives may be used. No special quartz lenses are necessary. Nearly all oil-immersion lenses fluoresce and cannot be employed. The intensity of the fluorescence of the bacilli is not enough to allow the use of a binocular microscope.

The slides are first examined under low power and are searched systematically for yellow specks. The bacilli will, of course, be extremely small under this magnification, appearing only as minute rod-shaped flecks of yellow in the green field. They are, however, easily seen, and after a short period of practice, it is possible to search an entire slide under the low power in less than twenty minutes. As in the Ziehl-Neelsen stain, there are acid-fast fluorescent artifacts, thus, confirmation under higher power is necessary. With the high-dry lens it is possible to identify the tubercle bacillus more closely. It appears as a long, thin, irregularly stained rod that is pale whitish yellow. The bacillus usually has a slightly irregular outline.

Smears from a wide variety of sources have been examined by this method. These include exudates and caseous material from pleural cavities, meninges, bone and tendon sheaths, as well as sputum and gastric lavages. With few exceptions smears from these locations showed few artifacts, and these were easily differentiated from tubercle bacilli. Smears made from lymph nodes may be unsatisfactory because of the large number of artifacts. In sputum the number of artifacts is occasionally large enough to interfere with examination of the smear. Thus, in the hands of an inexperienced examiner, false positive reactions may be reported. In the examination of seventy-six sputum specimens from healthy medical students, only two were found with so many artifacts that examination of the slide was unsatisfactory.

*Senior intern, First Medical Service, Boston City Hospital

†Formerly, student fellow, Department of Pathology, Tufts College Medical School

In a series of 15 color-blind medical students, 10 found more tubercle bacilli in the examination of positive smears stained with the fluorescent method than they did in smears stained with the Ziehl-Neelsen technic.

Richards⁶ reports that when the two stains are used in sequence on the same areas of the slide, more organisms appear with the fluorescent than with the Ziehl-Neelsen method

SUMMARY

The advantages of the fluorescent staining of the tubercle bacillus over the Ziehl-Neelsen technic are many. It requires only about three and a half minutes to stain a slide completely without the use of heat. Because of the use of lenses of lower power it is possible to examine a smear completely in less than twenty minutes—a point that has been made by Lind and Shaughnessy.⁷ This method is considered more accurate than the Ziehl-Neelsen

technic. The technic can be used safely for the screening of large numbers of sputums, the Ziehl-Neelsen method being restricted to the few specimens in which questionable fluorescent particles are encountered. Color-blind persons can identify the tubercle bacillus more readily with the fluorescent than with the Ziehl-Neelsen

MEDICAL PROGRESS

WAR WOUNDS OF THE ABDOMEN (Concluded)

CLAUDE E. WELCH, M.D.*

BOSTON

Liver The liver is frequently involved in abdominal wounds, and almost always in right thoraco-abdominal wounds. Consequently, x-ray films often show shell fragments within the liver shadow. Since these foreign bodies are well tolerated and their removal difficult, they are usually left in situ. This led to rather conservative therapy of liver wounds early in the war. It soon became evident that a more radical technic was required and that adequate drainage was necessary to avoid bile peritonitis, bile empyema or subdiaphragmatic abscesses. Although Betts²⁷ believes that a wound produced by a fragment 3 mm. or less in diameter, may be treated conservatively, the usual opinion is that any penetrating wound of the liver demands exploration, suture of any laceration of the diaphragm and the establishment of adequate subcostal drainage. This is due to the fact that the tiniest fragment may injure a large biliary radical.

The other major problem in the initial surgery of liver wounds is the control of hemorrhage. In the 829 patients studied by Madding, Lawrence and Kennedy,²⁸ spontaneous hemostasis had occurred at the time of operation in 91 per cent. Various methods have been employed to control active bleeding. Fibrin foam or a hemostatic gelatin sponge should be ideal but was not available for this purpose. Large, deep sutures through the liver are often effective, but their use is hazardous,

because they may initiate even more profuse bleeding. A tag of omentum may be placed in the defect. A detached portion of the rectus muscle may be of help. Large gauze packs have not been too satisfactory. They do not act as an adequate drain and, if left in place too long, form a large cavity that is slow to obliterate.

Madding advises the use of temporary gauze packs or a Penrose drain with gauze laid against the oozing surface. The drain should be started on the fourth or fifth day, and completely withdrawn by the tenth to the twelfth day. In only 1 case was grave postoperative hemorrhage encountered. Wounds near the hilus were most serious because of the proximity of other vital structures.

Gall bladder and bile ducts These injuries are rare, and are nearly always associated with wounds of other viscera. Depending on the severity of the wound, an injured gall bladder may be treated either by suture and cholecystostomy or by cholecystectomy. Damaged ducts should be repaired. A successful two-stage repair was described by Park.²⁹

Spleen In World War I wounds of the spleen were treated by packing, with the result that mortality was high. Splenectomy was often performed, but the mortality was 100 per cent. In World War II the consensus was that splenectomy should be done whenever any treatment is warranted. The most interesting trend in the performance of splenectomy has been the widespread use of the transthoracic approach. Poole³⁰ found that the

*Instructor in surgery, Harvard Medical School; associate visiting surgeon, Massachusetts General Hospital; formerly Lieutenant Colonel, U. S. A.

mortality in 159 cases removed by the trans-abdominal route was 29.5 per cent. The mortality in 171 cases of transthoracic splenectomy was 19.8 per cent. A transthoracic approach for strictly abdominal wounds, however, should not be made because of the possibility of fecal contamination of the pleura.

Kidneys Wounds of the kidneys are treated either by packing or by nephrectomy. A conservative attitude is adopted whenever possible, nephrectomy being retained for severe damage to the vessels at the pedicle or to the renal pelvis, or for complete fragmentation of the organ. In the Second Auxiliary Surgical Group nephrectomy was required in 28.1 per cent of all cases, gauze packs were not favored. Postoperatively, urinary drainage generally continues for several days. A persistent urinary fistula, secondary hemorrhage and sepsis furnish the usual postoperative complications.

Ureter In any wound in which it may have been damaged it is necessary to expose the ureter, since overlooked wounds lead to death from urinary extravasation. Tiny wounds can be sutured. High transections may be treated by a telescoping anastomosis. If the transection is low, the ureter may be reimplanted in the bladder. Kimbrough³⁰ advises suture of the injured ureter over a catheter and proximal diversion of the urinary stream.

Bladder All patients suspected of bladder wounds should be catheterized preoperatively. Kimbrough³⁰ stresses the diagnostic value of this procedure and also advises digital rectal examination with the catheter in place.

Wounds are treated by suture and by suprapubic cystotomy. Urethral catheter drainage is not sufficient in itself to assure an empty bladder, and therefore must not be used to the exclusion of a suprapubic tube. It is also necessary to provide adequate drainage to the space of Retzius. The bladder is rarely involved alone, so that a careful search should be made for other visceral damage. Thus, Michels,² in 155 cases, found bowel damage in 88 per cent. There were no deaths when only the bladder was involved, and only 1 patient developed perivesicular infection.

Prostate and urethra The value of primary repair of the membranous or prostatic urethra has been emphasized by Leadbetter.³¹ He has described a method that can be carried out entirely through a suprapubic approach, and has obtained healing without stricture. The essentials of his technic comprise the passage of a urethral catheter, the accurate visual repair of the urethra, when possible, through the floor of the bladder and the anchoring of the dislocated prostate to its normal position in the perineum by deep stay sutures.

If this procedure cannot be carried out as a primary measure, a suprapubic cystotomy may be done, to be followed in a few days by a urethral repair. The importance of early repair is shown by

the statistics of Conger,³² who observed severe, non-dilatable strictures in cases that were repaired six weeks after injury, whereas in those done soon after wounding the patients did well.

Pancreas Wounds of the pancreas carry a high mortality chiefly because other viscera are injured at the same time. The usual treatment has been to establish drainage with a Penrose wick. The development of acute pancreatitis or skin irritation at the site of the drain frequently occurs if the patient survives.

Major Vascular Wounds

Patients with wounds of the aorta do not live to reach the surgical hospital. On the other hand, major wounds of the vena cava and the iliac, portal or superior mesenteric veins may be found on the operating table. These patients, according to Jarvis, Byers and Platt¹⁴ show a characteristic clinical syndrome. Response to shock therapy is slight, but it is usually possible to raise the systolic pressure to 50 or 60. The pressure falls to 0 as soon as the peritoneal cavity is opened, and remains at that level until the bleeding is stopped.

If the wound can be controlled rapidly the patient may survive. Suture of a tangential wound or ligation of the vessel may be done. Packs or tangential clamps have been used in desperate cases, but are not recommended. Suture involves a greater hazard because of the possibility of embolism, so that ligation is preferred.

In 75 cases of major vascular injury observed at the Second Auxiliary Surgical Group the mortality was 73 per cent. No patient in the 8 cases in which the vena cava was ligated or sutured above the renal vessels survived. The major causes of death were hemorrhage (27 cases), anuria (12 cases) and pulmonary emboli (4 cases).

Swingle and Flynn,² discussing retroperitoneal hematomas, state that "the real significance [of such a hematoma] other than for the clinical signs which are indistinguishable from those of a viscus perforation lies in the fact that it may obscure injury to vital retroperitoneal structures." Therefore, if the position of the hematoma could indicate possible injury to the ureter, posterior aspect of colon, rectum, duodenum or bladder, these areas should be explored. Churchill³³ has pointed out that retroperitoneal hemorrhage is not a hazard per se unless the hemorrhage continues. In such an event the bleeding must be controlled.

Closure of the Incision

Insecure abdominal closure will lead to a high incidence of wound dehiscence, whereas if the closure is carried out by ordinary civilian methods there will be many serious infections. Thus, Jarvis, Byers and Platt¹⁴ found that in the first 28 abdominal cases done by their surgical team there was dehiscence in 6 cases. Thereafter, they changed the

method of closure in a radical fashion, and in the next 100 cases had no disruptions. They recommend the following method. The peritoneum is closed with a running catgut suture. The posterior and anterior rectus sheaths are then closed with interrupted nonabsorbable sutures. This is further reinforced by numerous through-and-through sutures placed about 2 cm lateral to the incision and about 1 cm apart. A strip of vaseline-soaked gauze is placed between the skin edges down to the fascia. This gauze is removed in forty-eight hours. This same method is recommended by Churchill,²² and others.

Certain methods of wound management were abandoned as experience increased. Laparotomies conducted through wounds of entrance and exit were found to be generally unsatisfactory. When colostomies were brought out through the main incision, the problems of infection and dehiscence were enhanced.

When a large part of the abdominal wall has been destroyed, tight closure will be impossible. Ogilvie²⁴ recommends the suture of a strip of vaseline-soaked canvas over the exposed bowel. This can be removed when granulations have formed over the bowel, and the hernia treated subsequently.

Evisceration

Patients with evisceration show an unusual degree of shock, and have a poor prognosis. Bradford, Battle and Pasachoff²⁵ found a mortality of 76.9 per cent in their cases with evisceration (omental eviscerations were not included). Childs²⁶ found a 10 per cent incidence of evisceration in a series of 3154 cases of abdominal and thoracoabdominal wounds. The small bowel, omentum and colon were the usual organs involved, comprising 87 per cent of the group. The evisceration occurred more frequently at the wound of exit. The over-all mortality was 40.3 per cent — nearly twice as high as that in corresponding wounds without evisceration. If the colon alone had protruded the mortality was 57.5 per cent, and if the omentum alone, 37.2 per cent.

Thoracoabdominal Wounds

A full discussion of this subject is beyond the scope of this paper, but several important features of this group of wounds must be mentioned. Excellent analyses have been presented by Snyder,²⁷ DeBakey,²⁸ Wylie et al.²⁹ and Mason and Imes.³⁰ Shorter series are described by Welch and Tuhy,³¹ Sanger³² and Tuttle.³³ The features are as follows: any wound in which the diaphragm may have been traversed must be explored, with few exceptions, surgery of chest wounds should be done first in multiple wounds, thoracoabdominal wounds and combined intrathoracic and abdominal wounds, most thoracoabdominal wounds are best handled first by the thoracic approach, a celiotomy being performed only if the abdominal wounds cannot be

cared for by the transdiaphragmatic route (the relative advantages of the various types of abdominal and thoracic incisions are described by Betts³⁴), the incision, which should usually be made through the ninth and tenth rib bed or interspace, may be extended 2.5 to 5 cm on to the abdominal wall if necessary³⁷ — and small accessory muscle-splitting incisions may be made for subdiaphragmatic drainage or exteriorization of colon, but extension onto the abdominal wall is not approved by some authorities, because the wound may break down^{37, 38}, and the diaphragm must be sutured with non-absorbable material, preferably in two layers.

A summary of the experience of the Second Auxiliary Surgical Group is presented in an excellent article by Wylie et al.²⁹ In 3532 patients with abdominal wounds, 25.5 per cent of cases were thoracoabdominal. The missiles had entered the abdomen from the thorax in 837 cases, and from the opposite direction in only 66. The right and left sides were equally involved. The authors discuss preoperative and postoperative treatment in detail, stressing the importance of accurate x-ray examination, the use of intercostal novocain block and postoperative bronchoscopic aspiration.

With right-sided wounds the liver was involved in 407 of 435 cases, followed in order, by the kidney, colon, stomach, small bowel, duodenum and gall bladder. On the left side, in 448 cases, the spleen was injured in 272, the stomach in 167, and the colon in 145. The liver, left kidney, small intestine and pancreas were involved with diminishing frequency. In 362 cases the whole operative procedure was carried out through the chest.

Mortality rates decreased progressively from 36.7 per cent in 1943 to 20 per cent in 1945. Wounds of five or more organs were uniformly fatal. In 234 fatal cases, the cause of death was shock in 130, peritonitis in 20, pneumonia in 17, renal failure in 15 and pulmonary emboli in 10.

Blast Injuries

Blast injuries of the abdomen were relatively infrequent in land warfare. Underwater explosions provided many small groups of cases that have been reported by various authors.

The mechanism of blast injury has been investigated by Greaves et al.⁴¹ and by Webster and his associates.⁴² They found that solid viscera are rarely affected. If the intestine is full of fluid it is also relatively immune, but if gas is present, there will be damage. Lesions were never found in animals in which the gastrointestinal tract was empty. Two types of lesion are found in fatal cases: complete perforation of the wall and hemorrhagic discoloration of the wall.

A typical sequence of symptoms is described by Webster et al.⁴² as follows: a sensation of a tremendous blow on the abdomen at the time of the explosion, profuse vomiting, often of blood, bloody

diarrhea, severe abdominal pain, fever, the temperature averaging 102°F, rigidity of the abdominal wall at one time or another, a white-cell count of 11,000 to 30,000, prolonged elevation of the sedimentation rate, and weight loss

Operation is indicated for frank perforations soon after injury, for late perforations following hemorrhagic infarction and for drainage of abscesses⁴⁶ The decision is often difficult because of associated pulmonary damage It must be made within twelve hours, however, and doubtful cases explored⁴⁶ In 7 cases operated on by Goligher, King and Simmons,⁴⁷ twenty perforations were found in each case, ranging from 1.0 to 3.7 cm in diameter The mortality in all cases is about 25 per cent

Postoperative care Essential features of the postoperative care include replacement and maintenance of a normal blood volume, with constant check by copper sulfate studies of the hematocrit and serum protein — if blood volume determinations are available they will be of great value, the intravenous administration of adequate amounts of fluid, sugar, salt and, if available, protein, continuous nasogastric suction, not by means of Miller-Abbott tubes, which, in general, are too complicated for field use, but by a Levin tube, which is as effective if it is introduced before operation and maintained, accurate observation of the urine, special attention to the lungs to prevent pneumonia — intercostal block, tracheal or bronchoscopic aspiration may be necessary, chemotherapy, and gradual restoration of food intake as improvement occurs It is of extreme importance that these cases are non-transportable for a period of ten to twelve days

REPARATIVE SURGERY

This secondary surgery is performed in large hospitals in the Zone of Communications In the Army general hospitals overseas the care of abdominal wounds was resolved into the following main categories the management of colostomies, the drainage of residual abscesses and the care of septic wounds, and the treatment of intestinal obstruction These topics are discussed below in order

Management of Colostomies

Colcock²¹ has stated that few colostomy patients escape without some complication, such as wound infection, wound separation, retraction of the colostomy, evisceration or the development of abdominal-wall, intra-abdominal, subphrenic or retroperitoneal abscesses He suggests that practically all could be avoided by adequate mobilization of the colon I have seen complete dissolution of the incision when the wound of entrance has been used as the exploratory incision and the colostomy brought out through it, serious abscesses after colostomy has been performed distal to the perforation and intraperitoneal retraction of the sigmoid colostomy when mobilization has not been sufficient. With increasing

experience, these errors in initial surgery became less numerous

Horsley and Michaux⁴⁸ observed the results in 111 cases in a general hospital in Italy, in which the colostomy closed in 40 cases and in which new colostomies were required in 5 because of the complications listed above Whether or not a colostomy was to be closed was dictated to some extent by transportation facilities The general rule was to evacuate the patient to the Zone of the Interior for closure if he was debilitated or had other severe injuries If closure was to be done, the usual time was six weeks after injury The procedure should not be attempted in the presence of wound sepsis or if peritonitis has existed within six to eight weeks, nor should it be done until all plastic surgery on the lower bowel, anal sphincter, urinary bladder or perineum has been completed

It was found that a few minor perforations can be closed and the loop exteriorized — the perforations will heal, and the loop will then retract within the peritoneal cavity Since all types of colostomies tend to retract, a glass rod should always be used with loop colostomies, and the bowel should be opened in the long axis on the oral side of the rod

There was no mortality following closure, and fecal drainage occurred in only 1 case The bowel could usually be closed with transverse sutures In a few cases resection and end-to-end anastomosis were necessary The bowel was always placed within the peritoneal cavity

Gregg and Moseley⁴⁹ believe that digital examinations of the stoma will determine the best type of repair With a loop colostomy, pressure with the finger will invaginate the posterior wall of the bowel into the peritoneal cavity To close it, the colostomy is freed and turned in with two layers of transverse sutures If a long, thin spur is present, it can be cut with crushing clamps Closure is effected in the same fashion after tension on the bowel has been relieved by partial opening of the peritoneum A thick spur indicates either a mesenteric artery from a rotated loop of colon or a loop of small bowel In this event the peritoneum must be opened widely If there is a constricted or retracted colostomy, plastic repair is done at the site of the stricture, which is opened longitudinally and closed transversely The authors fear resection with end-to-end anastomosis — an apprehension that is unfounded in view of later reports

Drainage of Residual Abscesses and Care of Septic Wounds

Wound care does not differ from that encountered in civilian practice A conservative attitude may properly be taken so far as residual abscesses are concerned Ogilvie^{31, 50-52} has observed that practically all except subphrenic and pelvic abscesses tend to burrow to the surface, discharging spontaneously through the wound or incision In my experience

many cases of subdiaphragmatic infections have subsided under adequate chemotherapy, and operation need not be considered urgent unless an undrained collection of bile is suspected. Pelvic abscesses can be drained easily through the rectum as soon as they become fluctuant. It is not advisable to wait for spontaneous rupture, since this may be delayed for a long period.

Treatment of Intestinal Obstruction

Obstruction of the small bowel is frequent after war wounds, probably because of the extreme trauma, hemorrhage and infection. This complication may appear at any time in the early convalescence or thereafter. Conservative therapy is unlikely to be successful except soon after the initial laparotomy, when the adhesions are still of a plastic type. Later, laparotomy will be necessary. Many adhesions are usually found, and it is generally unwise to attempt to free them all, only the obstruction can be relieved in most cases.⁴² Enterostomy may be necessary if the lumen of the bowel has been compromised by previous obstruction.

The late care of thoracoabdominal wounds in an overseas general hospital was discussed by Fox.⁴⁴ Of 270 patients only 43 per cent required further operations, 36 per cent secondary closure of wounds, 11 per cent thoracotomy for empyema, 5.2 per cent exploration of the subphrenic region, 4.4 per cent colostomy closure and 1.8 per cent decortication. The mortality was 2.6 per cent. Complications consisted chiefly of empyema and subphrenic abscesses.

RECONSTRUCTIVE SURGERY

Reconstructive surgery is performed in the hospitals of the Zone of the Interior. As in the overseas general hospitals the main problem is that of colostomy closure. In addition, wounds of the rectum are closed, incisional hernias are repaired, urethral strictures may need operative intervention, occasional cases of intestinal obstruction require operation, and some foreign bodies are removed.

Colostomy Closure

Many papers have appeared on the subject of colostomy closures. At present all the cases in which closure has been done in the general hospitals of the Army are being collected by Poer⁴⁵ and will be published shortly. It is his impression that intraperitoneal end-to-end anastomosis should be performed. He has found a high degree of immunity to infection in these patients and has been unable to prove that preoperative or postoperative chemotherapy has improved the results. There were only 17 deaths in over 2000 cases.

Several other surgeons have presented smaller series but have reached essentially the same conclusions. Roettig, Glasser and Barney⁴⁶ advise the

intraperitoneal closure because there may be unpleasant sensations when the bowel is incarcerated on straining or defecation, because ventral hernia is frequent after extraperitoneal closure, and because an extraperitoneal closure offers a good site for internal herniation and strangulation of small bowel. Foisie⁴⁷ also advocates an intraperitoneal closure. He was able to prepare most of his cases by crushing the spur.

Keene⁴⁸ notes that if two colonic stomas are in such proximity that the same dressing covers both, feces will progress from one to the other. He states that a patient with a colostomy invariably builds up a fecal impaction in the distal loop while being evacuated to the United States. He believes that resection and open end-to-end anastomosis are so satisfactory that, when a proximal colostomy is made for a wound in the distal colon, the colon should be completely transected and the two stomas placed at least 6 cm. apart.

Saunders and Halperin⁴⁹ list the most frequent problems encountered in colostomy closure as subcutaneous herniation of the bowel, complete absence of a spur, interposed foreign bowel or mesentery between colostomy limbs, varying degrees of rotation of limbs, secondary perforation or fistulas, inflammatory or granulomatous masses and musculo-fascial defects in the abdominal wall. They believe that the anatomic repair of these defects requires an intraperitoneal operation. They favor and describe the Pauchet closure.

Hamilton⁵⁰ found that extraperitoneal closure was associated with a much higher incidence of complications than intraperitoneal. Recurrent fecal fistula and intestinal obstruction were frequent after extraperitoneal closures.

Advocates of extraperitoneal closures include Pilcher and Nadeau.⁵¹ Shallow, Eger and Tourish,⁵² from civilian experience, have described a method of closure that falls in the same group.

A critical survey of these various reports suggests the following conclusions. After proper preparation, the mortality following any type of closure is extremely low. Plastic and extraperitoneal closures occasionally develop temporary fecal fistulas or intestinal obstruction. Postoperative barium enemas will demonstrate a surprising amount of stenosis in many cases, even though the patients are clinically free of symptoms. The complications can be avoided by resection of the involved bowel, an open end-to-end anastomosis and secondary closure of the abdominal wound. This is therefore the preferable method.

In colostomy closure various other problems arise. One of the most important is the selection of the proper time for operation. All agree that the other operative procedures in the pelvis must first be completed, and that the patient must be in a good state of nutrition. Preferably, he should be within 10 pounds of his normal weight.

The exact method of preparation of the bowel for closure has varied considerably. Usually, meticulous mechanical cleansing of the bowel was associated with several days of preoperative chemotherapy in the form of sulfasuxidine, sulfathalidine or sulfaguanidine. Preoperative barium studies of all the distal and proximal bowel, as well as x-ray visualization of any fistulas present, are important.

Closure of Rectal Wounds

Hamilton,⁶¹ describing the operative technic, states that these wounds are serious, because there is usually much scar tissue in the rectal wall and often a stricture or abscess as well. A completely defunctioning colostomy is essential. A generous incision should be made with removal of the coccyx and the fifth and fourth sacral segments if necessary. The rectal wall must be freed widely. Stenosis may be corrected by a longitudinal incision with transverse closure well away from the fistula. The fistula should be closed with two or three layers of sutures. Any associated foreign body that contributes to persistent sepsis is removed. The incision is allowed to heal by granulation.

Roettig, Glasser and Barney⁶⁶ state there are three important steps in closure of rectal perforations: adequate exposure, with removal of the coccyx and as much of the sacrum as necessary, as wide mobilization of the rectum as possible, both laterally and in front of the sacrum, and interposition of some fat or muscle tissue between the portion of the rectum containing transverse closure and the sacrum before the skin is closed. The wound is closed without drainage.

Laceration of Anal Sphincter

In such cases a colostomy is essential, according to Roettig, Glasser and Barney.⁶⁶ The sphincter is mobilized through a semicircular incision 3 cm from the mucocutaneous margin. If closure is still impossible, the defect should be reduced as much as feasible. A second stage is carried out several weeks later after sphincter-control exercises and daily dilatation. Sphincter action and control must be tested before the colostomy is closed.

Intestinal Obstruction

Barney, Roettig and Jones⁶⁴ observed that in the last year in the Rhoads General Hospital, mechanical obstruction was found in a ratio of 1:18.5 cases. The incidence in the small bowel was three and a half times that in the large bowel. In the former all types of obstruction were found, whereas in the colon the most frequent cause was a small lumen following colostomy closure.

In the experience of these authors the incidence of strangulation of the small intestine or marked interference with blood supply was far greater in war wounds than the usual 10 per cent figure in civilian practice. They therefore advocate early laparotomy

rather than the use of the Miller-Abbott tube. If the obstruction is in the colon, an attempt is made to delay operation long enough to give the patient an adequate amount of the sulfonamides. Thereafter, a resection and end-to-end anastomosis are done.

Removal of Foreign Bodies

Intraperitoneal foreign bodies are preferably removed at the time of initial surgery. Large shell fragments that have not been recovered may be removed in the Zone of the Interior. Those that contribute to persistent fecal or urinary fistulas, osteomyelitis or continued purulent discharge from a wound must be taken out. In addition, many that are in close relation to large vessels or to the hollow viscera should be removed. Those buried in the retroperitoneal musculature and in the liver usually produce no symptoms and may be left in place.

Repair of Hernia

No special problems are presented except that fascial repairs of hernias are frequently necessary.

Late Urinary Problems

Kimbrough²⁰ found that of the urogenital injuries seen in the general hospitals in this country, the kidneys had been wounded in 14.0 per cent, the ureter in 3.4 per cent, the bladder in 14.5 per cent, and the external genitalia in 68.1 per cent of patients. Nephrectomy had been performed in only 2.4 per cent of patients with kidney wounds. Prather⁶⁵ observed that nephrectomy was necessary in 2 of 3 cases of ureteral fistula evacuated to the Zone of the Interior.

The importance of early repair of the urethra²² and the difficulty attending late attempts have been stressed by Conger.²² Stricture is frequent after late repair, and dilatation is often impossible.

Rectovesicocutaneous fistulas are the most difficult late sequelae of bladder wounds to treat. Roettig, Glasser and Barney⁶⁶ state that the fistulas usually heal spontaneously if colostomy, suprapubic cystostomy and inlying urethral catheters are used.

Cystitis and epididymitis were also found to be frequent complications after bladder wounds.

* * *

In conclusion it might be appropriate to list several of the unsolved problems of abdominal surgery in warfare. The first and the most important is an accurate appraisal of the role of chemotherapy, both in the prophylaxis and in the treatment of peritonitis and other types of sepsis.

The prophylaxis of peritonitis has not yet been possible. Early in the war many soldiers took sulfonamide tablets by mouth immediately after they were wounded. It is obvious that the sulfonamides were useless in this fashion. The introduction

of streptomycin and of the relatively nonabsorbable sulfonamides, sulfasuxidine and sulfathalidine, however, offers a method to reduce significantly the number of virulent organisms in the gastrointestinal tract. It may be possible to develop a technic for the oral administration of these drugs for a few days before battle that would be valuable.

So far as the therapeutic administration of the sulfonamides and penicillin is concerned, it is impossible to assess their value satisfactorily. The variability of the types of wounds, the absence of any adequate control series and the omission of details of therapy in many records indicate that opinions rather than facts have been recorded. Furthermore, compared with the dosage that is employed today, penicillin was not available in sufficient quantities to influence the course of an established peritonitis.

Lyons^{46, 47} emphasized the fact that adequate excision of devitalized tissue is much more important than the bacterial flora of the wound. He further stated as follows:

Sulfonamide therapy has been shown to be adequate for the wound in danger only of hemolytic streptococci. Penicillin is the drug of choice for all other wounds subject to invasive infections. No virtue is attached to combinations of penicillin and a sulfonamide compound as the treatment of infected wounds.

He concludes that local chemotherapy is unnecessary and undesirable and that penicillin administered parenterally is the chemotherapeutic agent of choice.

Imes,⁴⁸ discussing traumatic surgery of the abdomen, believed that the sulfonamides and penicillin were about equally effective in the treatment and prevention of peritonitis and that there was little doubt that chemotherapy played a significant role in the lower incidence of peritoneal infections following abdominal injuries. Drye⁴⁹ agreed that penicillin and the sulfonamides were important, but found it impossible to assess them accurately. He considered the mortality significantly lower, however, in the series treated with penicillin than in that in which sulfonamides were employed.

A second problem is concerned with the resuscitation of the wounded. Why is it that many patients, especially those with abdominal wounds, cannot be brought out of shock? Despite blood replacement and adequate surgery the blood pressure remains low, and death occurs in twenty-four to forty-eight hours. It is generally believed that overwhelming infection is present, but further clarification is needed.

A third problem is that of the so-called "multiplicity factor." Why is it that a man with five wounds of the small intestine has an excellent chance of survival, whereas a single wound of five viscera is almost uniformly fatal?

Moreover, the technical management of wounds of the colon demands further consideration. When one realizes that practically all the abdominal surgery

in general hospitals in the Zone of the Interior is concerned with the management of colostomies, it can be appreciated that any safe method whereby the convalescent period could be shortened would be of value. Thus, Imes⁴⁸ has observed that "the contention of those who hold that all wounds of the colon should be exteriorized because of its poor healing tendency and greater than apparent tissue damage from shell fragments is not supported by our experience." In particular, then, is there a place for primary closure of wounds of the colon, or is this such an unsafe procedure in the hands of the ordinary surgeon that it should not be countenanced? Also, what is the best method of management of severe wounds of the right portion of the colon?

Finally, in common with other extensive wounds, what is the explanation of postoperative renal failure? This is one of the most important causes of death in patients who survive the period of shock.

CASE 33321

PRESENTATION OF CASE

First admission A twenty-nine-year-old Jewish housewife was admitted to the hospital because of diarrhea

The patient's illness dated from an automobile accident nine years previously, which was followed by a nervous breakdown At that time she was supposed to have had a spine injury, which required six months' treatment, and during the convalescence she developed diarrhea (six to fifteen movements a day), which continued more or less constantly until admission to the hospital There was no blood or mucus but merely watery diarrhea Treatment by many physicians in several parts of the country gave no relief, and four years before entry she was explored at an outside hospital Dilated portions of small bowel, which were about the size of the large

bowel, with other areas of constriction and marked thickening of the wall, were noted There was marked fusion of the mesenteric lymph nodes, with the formation of large masses The mesentery was extremely friable and bled readily The diagnosis was thought to be tuberculosis of the small bowel extending from the ligament of Treitz to within 75 cm of the ileocecal valve The patient improved markedly following laparotomy, and three weeks later she had the first formed stool in a year She spent about six months in Arizona, felt much better and gained about 30 pounds Two years later, however, the diarrhea and emotional upsets returned, and the following year she was studied at another hospital, where tuberculosis was supposedly ruled out by x-ray examination and skin tests A diagnosis of ileitis was made at that time She continued to have six to fifteen movements a day, remained somewhat high-strung, tired easily, and lost about 20 pounds

Physical examination revealed a small, thin, poorly nourished woman with a high diaphragm and tympany over the normal liver dullness On the left side of the abdomen a large mass was palpated and percussed 8 cm below the costal margin No shifting dullness or other evidence of fluid was found The abdomen was slightly distended and felt doughy

The examination of the blood and urine was negative The stools were liquid and guaiac negative A barium enema required nearly three times the usual quantity for filling The colon was grossly

dilated and atonic. The ileum would not fill. There was slight deformity in the region of the ileocecal valve, but the mucosa was apparently intact. The hepatic flexure rose unusually high, whereas the splenic flexure was displaced downward, the entire abdomen appeared more dense than usual, possibly due to ascites. There were no gas-filled loops of small bowel. A gastrointestinal series revealed the stomach to be markedly displaced to the right and upward, there was a definite delay in emptying of the jejunum, with marked distortion. There was one long loop on the left side, about twice the normal size, that remained filled until the six-hour examination. After four hours the terminal ileum was fairly well filled and appeared small and slightly irregular, with the patient upright, fluid levels formed in the dilated small bowel but no gas was present. Examination of the chest was negative except for the unusually high diaphragm. She was discharged on the fourth day.

Second admission (one and a half years later). The patient was fairly well until seven months before entry, when she developed vomiting attacks that increased in severity. There appeared to be no exciting cause, and at the time of admission they were occurring every forty-eight to seventy-two hours, always preceded by nausea and occurring during the day. Despite this she had gained weight and felt much better than she had two years previously.

Physical examination revealed clubbing of the fingers and a doughy, tender abdomen. The spleen was palpable two fingerbreadths below the left costal margin.

Routine examination data were negative, and a barium enema revealed a deformity of the ileocecal valve and a dilated terminal ileum. On the second day a laparotomy was performed. At the operation a loop of small bowel was found glued to the abdominal wall, the intestine was greatly thickened, as was the mesentery of the small bowel, which was quite firm. There was interadherence of loops of small bowel and the mesenteries, and an enormous loop of jejunum could be elevated into the wound. A short circuit was performed between the distended, thickened jejunum and a piece of comparatively healthy, normal-sized small bowel. It was estimated, however, that at least half the small bowel was involved and possibly more. Areas of bowel that were obviously previously diseased could be seen in all quadrants of the abdomen. A biopsy of jejunum showed chronic inflammatory changes of a non-specific nature.

The patient improved and was discharged about one month after admission.

Third admission (six and a half years later). The patient returned for evaluation of a therapeutic abortion. She was two and a half months pregnant. Because the patient was free from symptoms, abortion was not performed.

Fourth admission (three years later). The patient had been delivered of an infant by cesarean section two and a half years previously and subsequently developed sudden marked abdominal distention, with rupture of the operative sutures. Following this the distention subsided spontaneously. Two and a half months before admission she had noted that her abdomen seemed unusually swollen, and it had remained so. There were no other symptoms.

Physical examination revealed only slight distention and tenderness of the upper abdomen and pitting edema of the lower edge, more so on the left, than on the right, with slight tenderness on the left.

Laboratory data, including total protein and nonprotein nitrogen levels, Congo red test and prothrombin time, were negative. A cephalin flocculation test was + in twenty-four hours and ++ in forty-eight hours. X-ray studies revealed clear lung fields and a high diaphragm, especially on the left. The heart and mediastinum showed a slight shift to the right. Diaphragmatic motion was active and equal. There was a gas bubble between the anterior portion of the right leaf of the diaphragm and the liver, with a fluid level beneath it, which was interpreted as bowel between the liver and diaphragm. The upper half of the abdomen showed a homogeneous increased density that extended below the right iliac crest and was inseparable from the liver shadow. A plain film of the abdomen failed to show bowel in the upper right abdomen and midabdomen, but no definite liver shadow was seen. Upright films confirmed the presence of an air bubble in a confined area beneath the right leaf of the diaphragm, possibly air in an unusually high stomach.

Some observers thought they could feel a rather soft, possibly cystic mass in the upper abdomen, which on one occasion was said to be ballotable to the left flank from the right upper quadrant.

A gastrointestinal series and barium enema one week after admission revealed the stomach to be markedly displaced to the right and slightly forward by a large mass occupying the left upper quadrant. The mass appeared somewhat lobulated. In addition the stomach displaced the duodenum and small intestine downward. There was a small area of radiolucency, resembling fat, within the mass. A normal spleen was not visualized as in the previous films. The liver was small. A barium enema revealed an extrinsic soft-tissue mass displacing the transverse colon from above and posteriorly.

An exploration was done on the sixteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR ALFRED KRANES. The remission of symptoms following a simple exploratory laparotomy seems extraordinary and raises considerable doubt regarding the diagnosis of tuberculosis of the small bowel.

As you might well imagine, this has been for me an extremely confusing problem and on first reading over the abstract I was completely bewildered. As I went over it more carefully it seemed to me that the patient's illness might be divided into two phases. The first, beginning at the age of twenty and ending at thirty, following the enterojejunostomy for obstruction, was characterized by symptoms resulting from the diseased small bowel. The second phase dated from thirty to the time of admission, when she was forty. According to the record, during the last ten years she was completely asymptomatic. Is that a fair assumption to make?

DR DANIEL S ELLIS Yes, after the operation at this hospital she was in perfectly good health.

DR KRANES We have therefore to consider two questions. What was the nature of the small-bowel lesion that caused the original symptoms? Secondly, what was the nature of this mass in the left upper quadrant that brought her to the hospital at the age of forty? Is it fair to ask whether this patient survived the operation or came to autopsy? The reason I ask, is that time is short and I do not want to waste too much time on the small-bowel lesion.

DR TRACY B MALLORY She survived the operation.

DR KRANES If that is the case, it leads me to believe that they do not know any more about the disease in the small bowel than has already been described in the previous operative note and in the record. If that assumption is correct, I can probably speak freely about the probable nature of the small-bowel disease. It seems to me that the likeliest explanation for all the small-bowel symptoms is the diagnosis that was subsequently made, namely, regional enteritis. That diagnosis explains the history of this patient's illness and the x-ray findings, as well as the operative findings, more satisfactorily than anything else I can think of. The one thing that disturbs me greatly about the history of this illness is the fact that no pain was mentioned during the early part of the disease. That is unusual in any extensive lesion of the small bowel. Is it true that this patient never had any pain?

DR ALLEN She had pain associated with nausea and vomiting before the first operation, the one done at another hospital.

DR KRANES The original description of the bowel, as well as that of the mesentery and the large lymph nodes, is quite characteristic of regional enteritis, particularly the enlarged nodes. Some surgeons advocate removal of such lymph nodes, since it has been claimed that they are the reservoir of residual infection and predispose to recurrence. The disease has been experimentally produced, or a reasonable facsimile of it, by injecting sclerosing substances into the mesenteric lymphatic vessels. The histologic picture in animals is almost indistinguishable from that in human cases. Furthermore, the operative findings at the second lapa-

rotomy are quite in keeping with the diagnosis of regional enteritis. It is characteristic for inflammatory changes to be produced between loops of bowel and for fistulous tracts to form eventually. There were none in this patient. There is nothing in the history or symptoms or operative findings that contradicts the diagnosis of regional enteritis.

So far as tuberculosis goes, I think that is most unlikely, since ulcerative tuberculosis of the small bowel is usually a terminal event in advanced pulmonary tuberculosis. I also believe that the course of the disease is strongly against tuberculosis.

I shall leave that for a moment and go on to the mass in the left upper quadrant. What was its nature? I am afraid that I shall need quite a bit of help from the X-ray Department. I must confess that this description is exceedingly confusing. There seems to be an implication of two masses, one on the right side that extends to the right iliac region without any evidence of bowel in that region, and another on the left side. I was allowed to look at these films yesterday.

DR RICHARD SCHATZKI I shall show you the outline of this mass, there was only one.

DR KRANES The other thing that confuses me is the statement that a normal spleen was not visualized, as in the previous films. That to me is an important statement, because if a normal spleen was visualized on previous films, the diagnosis that has occurred to me must be completely discarded.

DR ELLIS There is only one mention of the spleen in all the films taken over a period of fifteen years.

DR SCHATZKI No shadow of the spleen was visualized, unless one calls this peculiar mass the spleen.

DR ELLIS In the original examination Dr Holmes described the spleen, which I am sure is the same mass that subsequently increased in size.

DR SCHATZKI The original film was taken in 1936, and the mass at that time displaced the stomach to the right. In the next ten years it became eight times as large, displacing the stomach to the right and slightly forward and the colon downward.

DR KRANES How about the small bowel?

DR SCHATZKI There is nothing that can be added to the report.

DR KRANES This mass is much larger than it was originally. What interests me is why it was not found at exploration. The operative note said nothing regarding it. I should have expected that a mass of that size would have been described, but perhaps the emergency of the intestinal obstruction and the extensive disease in the small bowel prevented extensive exploration within the abdomen.

Dr Schatzki, was this mass separate from the left kidney?

DR SCHATZKI Yes.

Dr KRANES In other words, it was a gradually increasing epigastric mass, probably chiefly in the left upper quadrant, completely asymptomatic and unattached to the stomach, to the kidney and probably to the adrenal gland. That leaves us little else to consider.

One point to be decided is whether or not this mass was in any way related to the previous disease of the small bowel. It is difficult for me to connect the small bowel disease with the mass. Although it is true that regional enteritis not infrequently perforates and produces localized abscesses, it is impossible for me to believe that an abscess of this size could have been present for ten years without discomfort, fever or something in the way of symptoms. Furthermore, it is a most unusual site for an abscess. Finally, abscesses rarely attain the size described here. So I think I shall discard any relation between this mass and the previous small-bowel disease.

When one has multiple lesions and extensive disease within the abdomen, particularly a large mass in the left upper quadrant, the possibility of lymphoma comes to mind. Could the small-bowel disease have been lymphoma, and could the remissions have been due to the number of x-ray examinations she had had for many years? I hardly think that diagnostic x-ray doses could have produced this type of remission. The finding of large mesenteric nodes at the first operation is rather suggestive, but if she did have lymphoma, she must have cured herself spontaneously and I do not believe one can consider it seriously.

The next question to decide is whether the mass was solid or cystic. It seems to me that solid masses in this area and of this duration should have caused more in the way of symptoms. Furthermore, a large solid mass in this region should have been readily palpable. I am much more in favor of a cystic mass. The only cystic mass with which I am familiar in the left upper quadrant is a cyst of the spleen. That is the first thing that occurred to me, but as I studied the case more carefully, I hesitated to suggest it as a possibility because the condition is so rare. Yet I can think of no other explanation that fits all the findings in this case any better than a large cyst of the spleen. Actually, this patient had the proper background for such a diagnosis. Most of the cases described, of which there are not many, occurred in young women, and this started before the age of twenty-nine. A large proportion of them have a history of preceding trauma, which was present here. Most of these cysts, if that is what this is, contain old, brown, coagulated fluid, probably the result of the original hematoma.

In thinking of cystic diseases in this area, one also has to consider a dermoid cyst. They are extremely rare in the left upper quadrant, although

a few have been reported. What about the area of radiolucency. Is that striking?

Dr SCHATZKI No, not at all. I should not consider it definite.

Dr KRANES Other conditions to be mentioned, of course, are retroperitoneal sarcoma and fibroma. It seems to me that any malignant tumor in this area is ruled out by the duration of the disease. The most probable diagnosis, so far as I am concerned, is a large splenic cyst, the result of old trauma.

Dr EDWARD B. BENEDICT I should think that this might well have been a pancreatic cyst.

Dr KRANES That is a perfectly good suggestion. A large cyst in the tail of the pancreas can produce exactly the same picture, and I certainly should have mentioned it, but I see no way of differentiating a splenic and a pancreatic cyst clinically, except that the patient was a woman and had had an injury, two factors more in keeping with splenic cyst than with pancreatic cyst.

Dr ELLIS This patient came in with a purely mechanical problem. She felt perfectly well and had had no bowel symptoms for many years. At first, of course, we tried to tie this mass in the abdomen with the previous disease, but we could not do it in any way that seemed reasonable. Therefore, it boiled down to the fact that she had a mass in the abdomen. What was it? In addition to the conditions mentioned by Dr Kranes we thought of amyloid disease. Was this a huge amyloid spleen or liver? There was no positive evidence of amyloid disease in the laboratory tests. We were left with the diagnosis of cyst for the reasons that Dr Kranes has mentioned. The pre-operative diagnosis was cyst of the spleen, pancreas or mesentery, with betting on every one.

CLINICAL DIAGNOSIS

Cyst of spleen, pancreas or mesentery

Dr KRANES'S DIAGNOSIS

Cyst of spleen

ANATOMICAL DIAGNOSIS

Cyst of pancreas

PATHOLOGICAL DISCUSSION

Dr MALLORY Dr Allen, will you discuss the operative findings?

Dr ARTHUR W. ALLEN Dr Kranes has discussed the problem presented at the time of this woman's first admission, when she had the short-circuiting procedure, extremely well, and he arrived at as nearly a correct diagnosis as we could obtain from the exploratory operation. We short-circuited the obstructed loop of small intestine, and the pathological diagnosis that was made on the specimen was a nonspecific granulomatous lesion involving the small bowel—Crohn's disease or regional enteritis. She had had a peritonitis preceding or following the first exploration, so at the time of the

short-circuiting procedure it was difficult to re-explore extensively. She was not in good condition, and although we made some effort to discover the mass that had been described in the left upper quadrant, we could not get to it without too much dissection. So we short-circuited the loop, believing that that was all we should do.

She came back the last time with a perfectly huge mass, which could be felt on the left side. It was not hard but felt like a soft cyst. It was an interesting problem, and the various possibilities of cystic mass in this location were, of course, considered. All have been named that we did consider, but in going over the films with Dr. Schatzki I finally decided on the diagnosis of a cyst of the spleen. Cysts of the spleen always occur at a pole, and one had to assume that it was the lower pole of the spleen from which this mass had developed. The reason that it did not extend farther downward was that she had had peritonitis and the adhesions had kept it confined in that direction. It had followed the line of least resistance to fill the whole upper abdomen.

At operation we found that the mass was cystic, as expected, but that it arose from the pancreas. After determining that, we drained the cyst of 5 liters of fluid by suction, incised it and then anastomosed it to a loop of jejunum high up, just beyond the ligament of Treitz, the only piece of normal intestine that we could find nearby.

DR. MALLORY: This operation was essentially an internal marsupialization of the cyst.

DR. ALLEN: We had two choices. The other was to bring the edges of the cyst out through the abdominal wall, hoping that the sinus might eventually close, as they often do, if the sinus did not close, one could then implant the sinus into the intestine. The intestines were so interadherent, with every loop stuck to another, that it was not pleasant to think of having to go back into the abdomen again to implant a sinus tract. Within the last year or two Dr. Ralph Adams,* of the Lahey Clinic, has reported the anastomosis of pancreatic cysts to the small intestine, associated with an enteroenterostomy. We should have liked to do an enteroenterostomy here but could not do it. All we could do was to make an anastomosis to the jejunum. We took out a generous portion of the cyst wall for pathological examination.

DR. MALLORY: A section of the cyst wall showed it to be lined by columnar epithelium, similar in appearance to the lining of the normal pancreatic ducts. This was surrounded by dense fibrous tissue, and in the periphery there were numerous atrophic clusters of pancreatic acini. So we felt quite certain that Dr. Allen was correct in assuming that it had originated in the pancreas.

CASE 33322

PRESENTATION OF CASE

A forty-year-old housewife entered the hospital because of right chest pain and hemoptyses.

Thirteen years before entry she developed an upper respiratory infection followed by cough, fever and pleuritic pain on the right side. An x-ray film of the chest was said to have shown fluid at the right base. A sputum smear was negative for acid-fast organisms. After several weeks in bed she felt completely well except for a persistent, mild, slightly productive cough, which became accentuated when she had a "cold." Eight years before entry two pregnancies were interrupted on the basis of another chest x-ray film. Four and a half years before entry she began to have hemoptyses. X-ray films at that time revealed no abnormality and sputum examination was negative. Several months later she was admitted to a tuberculosis sanatorium, where x-ray examination revealed a shift of mediastinal contents to the right and considerable soft infiltration in the lower half of the right lung field. One sputum was reported positive, but ten succeeding examinations over the remaining seventeen months' stay at the sanatorium were negative. A right pneumothorax was performed, and this was maintained after discharge for a total of twenty-three months because of continued hemoptyses. Two years before entry she was admitted to another tuberculosis sanatorium, where bronchoscopy revealed that the right main bronchus was practically occluded just below the carina by a whitish tumor, which bled profusely on touching. A biopsy specimen was said to show undifferentiated or small-cell carcinoma. Bronchoscopic electrocoagulation of this tumor was carried out six times, and the patient received several courses of deep x-ray therapy. The hemoptyses, however, still continued. The patient also complained of right anterior chest pain, which was often severe enough to require codein for relief. Exertional dyspnea, easy fatigue, chronic cough and pallor had been present for several years.

On physical examination the patient was pale but appeared to be in no acute distress. The trachea was deviated to the right. The entire right lung field was dull to percussion. Over the upper portion there was bronchial breathing and tactile fremitus was increased. Over the lower portion, the breath sounds were absent and tactile fremitus was decreased. The heart was shifted to the right. There was a Grade II systolic murmur at the apex. The abdomen and extremities were normal.

The temperature was 98.6°F, the pulse 90, and the respirations 20. The blood pressure was 110 systolic, 70 diastolic.

Examination of the blood showed a red-cell count of 2,500,000 with 6.0 gm of hemoglobin, and

*Adams, R., and Nishijima, R. A. Surgical treatment of pancreatic cysts. *Surg., Gynec. & Obst.* 83: 181-187, 1946.

a white-cell count of 3500, with 75 per cent neutrophils. The urine was normal.

An x-ray film showed the right chest cavity to be smaller than the left. The mediastinum was retracted to the right. The right lung was completely airless except for a small bubble in the right upper chest. The left lung was clear.

Bronchoscopy on the third hospital day was unsuccessful because of profuse hemorrhage. On the sixth hospital day another attempt at bronchoscopy was made. Again there was profuse bronchial hemorrhage, and the patient died suddenly in respiratory failure.

DIFFERENTIAL DIAGNOSIS

DR CARROLL B. MILLER: I shall depart from the usual procedure in these case discussions and declare at the start that there can be little doubt that the diagnosis in this case is adenoma of the right main bronchus. I shall then discuss why other diagnoses are unnecessary and unlikely. That there may be other conditions associated with the adenoma warrants mention and deserves consideration, but they would be secondary and probably not necessarily related to the adenoma.

The age of the patient, the sex and the events in the thirteen-year-history of respiratory symptoms indicative of bronchial obstruction and associated collapse, pneumonitis and possibly bronchiectasis all point to an adenoma. Such a tumor has characteristically a long history, and thus, by virtue of its being admittedly a "benign tumor," does not cause progressive systemic decimating effects as are seen in a malignant tumor of the bronchus. Parenthetically, however, if the side effects of retained infection and pulmonary destruction occur in association with an adenoma or if the adenoma undergoes malignant degeneration as it is often claimed, the picture may be indistinguishable from that of a primary bronchiogenic carcinoma.

Three interesting details in the history must be discussed: the suspicion of tuberculosis, the biopsy report after bronchoscopy of carcinoma and the lack of response to x-ray therapy. It is not uncommon for a patient with any lung disease to be suspected of having tuberculous infection, and rightly so. Indeed, this patient's lung may well have shown tuberculosis at post-mortem examination, but that is not an important feature of the case. Hemoptysis, pleural effusion and x-ray signs of a soft infiltration in the right lower lung field are enough to make any diagnostician highly suspicious of tuberculosis, but sputum examinations, with one exception, were repeatedly negative for acid-fast organisms, and when bronchoscopy was finally resorted to, an obstructing tumor was found. The effect of this tumor in the main bronchus was sufficient to account for collapse, pneumonitis, pleural effusion and shift of the mediastinum—in

short, the picture that the patient showed on various occasions.

The microscopical diagnosis on biopsy two years previously was "undifferentiated carcinoma," and the tumor failed to respond to x-ray treatment. Without much doubt an undifferentiated carcinoma, thus probably highly malignant, would neither have permitted the patient to live two years nor have failed to show some response to radiation therapy. To quote Boyd's *Surgical Pathology*, "Surface cells [of these adenomas] may undergo squamous metaplasia which may suggest epidermoid carcinoma." Similarly, the nature and arrangement of the cells have sometimes provoked the diagnosis of "alveolar sarcoma, basal cell carcinoma or adenocarcinoma."

Let us consider the physical examination and roentgenologic picture of the patient. She had signs of extensive collapse of the right lung. Laboratory data indicated a probably chronic secondary anemia and tendency toward agranulocytosis, the results of chronic infection.

Taken all together, the history, physical findings, laboratory data, x-ray findings and bronchoscopic reports strongly suggest a benign, massively obstructing tumor of the right main bronchus, and this must have been a bronchial adenoma. Other lesions, such as a nonspecific granuloma, a foreign-body granuloma (the history is negative for aspiration) or a gumma (there is no Hinton report, and I assume that the serologic reaction of the serum was negative), may be dismissed as extremely rare and unlikely. The tumor, unfortunately, was malignant for this patient, since it was responsible for her demise, because of its extreme vascularity, hemorrhages were frequent, as is often the case with adenomas, and the cause of death was undoubtedly an inundation of the left bronchial tree, with consequent suffocation. It is this type of case that makes the surgeon so frequently prefer to proceed with lung resection without the benefit of cytologic examination of the neoplasm, once the gross appearance and site of obstruction have been determined by bronchoscopy.

No discussion of the pathology and surgical treatment of bronchial adenoma is complete without mention of the frequent, almost invariable, dumb-bell shape of the tumor, which characteristic justifies the abandonment of treatment by bronchoscopic morcellation and the adoption of resection at the site of that portion of the lung containing and blocked off by the tumor.

CLINICAL DIAGNOSIS

Bronchial tumor, type undetermined, with recurrent hemorrhages

DR. MILLER'S DIAGNOSES

Adenoma of right main bronchus, with bronchiectasis

Hemorrhage into left bronchial system

ANATOMICAL DIAGNOSIS

Bronchial adenoma of right main bronchus, with hemorrhage into left lung

PATHOLOGICAL DISCUSSION

DR BENJAMIN CASTLEMAN As Dr Miller predicted, this patient had a bronchial adenoma. The lumen of the right main bronchus was completely occluded by a pinkish gray tumor (Fig 1). The

The left lung was fluffy, and the bronchi and alveoli were filled with blood — an obvious aspiration of blood from the tumor.

Microscopically the tumor was a typical adenoma, with no evidence of carcinoma. The regional lymph nodes showed chronic inflammation.

Have you any comment, Dr Benedict?

DR EDWARD B BENEDICT The danger of serious hemorrhage from bronchial adenoma is a real one.

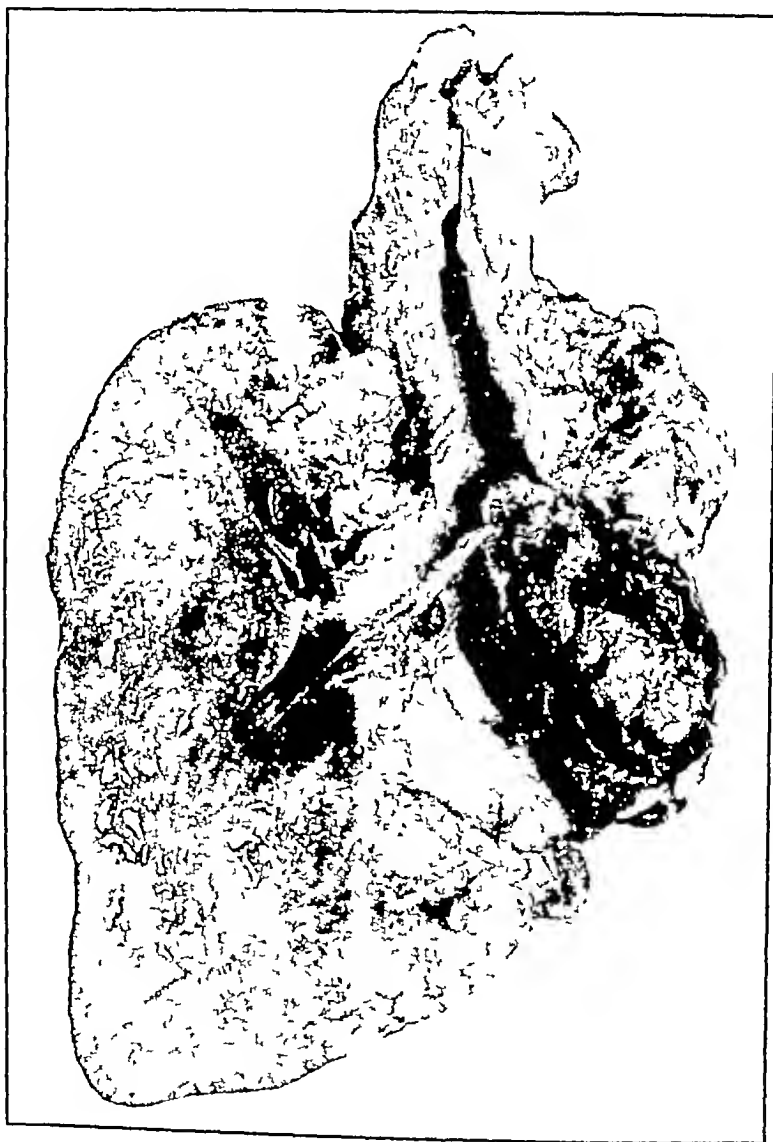

FIGURE 1

tumor was attached to the bronchial wall at a point approximately 1.5 cm from the bifurcation of the trachea and had grown proximally for a short distance into the trachea and distally into the secondary bronchi to form a large mass 9.5 cm long and 6.0 cm in diameter. Nowhere was the bronchial wall destroyed; the tumor merely grew down the lumens in pseudopod formation. Beyond the tumor there was bronchiectasis in the small collapsed lung.

If an adenoma completely blocks one main bronchus it means, of course, that the patient has only one useful lung. If serious hemorrhage occurs, either spontaneously or at the time of a bronchoscopy biopsy, it may mean drowning of the good lung by hemorrhage and a rapidly fatal termination. The experienced bronchoscopist can usually differentiate adenoma from carcinoma by the gross appearance. The former presents a smooth rounded surface

whereas the latter usually is nodular and irregular. On the other hand, there have been at least two cases of carcinoma in my experience in which a rather smooth polypoid finger-like carcinoma extended upward along the main bronchus, grossly simulating an adenoma. If the bronchoscopist is suspicious of adenoma from a long history of intermittent attacks of bronchial obstruction with repeated hemoptyses and so-called "pneumonia" and if, in addition, he finds a smooth grossly benign-appearing tumor blocking one main bronchus, he might do well to take no biopsy for fear of serious hemorrhage. The surgeon would then probably operate on the basis of the history, the x-ray examination, the gross findings at bronchoscopy and the probability of irreparable lung damage. The bron-

choscopist will have done his part by indicating the gross appearance of the tumor and the level at which it appears in the bronchus.

In the case under discussion, although the gross appearance of the tumor was that of a benign adenoma, there had been a previous report of carcinoma. The taking of a biopsy in this particular case, therefore, seemed especially important. Moreover, the tumor's position in this case, lying across the carina, made it somewhat inaccessible to surgical approach. Although many adenomas have been safely biopsied at bronchoscopy and even largely removed bronchoscopically, in retrospect one cannot help wondering what the outcome would have been if a pneumonectomy had been attempted without bronchoscopic biopsy.

WALTER PRENTICE BOWERS

Walter Prentice Bowers, of whose death on July 22 we are all aware, may well be ranked as the departed dean of the Massachusetts medical profession.

A life-long general practitioner of medicine and honored by Harvard University as such, a former president of the Massachusetts Medical Society and managing editor of the *Journal* for fifteen years, he was a man of stature among us.

To his older colleagues in the Society, he was a thoughtful, kindly friend; to many more, a wise counselor, to the youngest, we trust, an inspiring legend. Like Dr. Samuel Johnson,

he kept his friendships in repair, and his benign presence at all except the more recent Council meetings belied his ninety-odd years.

"Know ye not," said David to his servants, "that there is * * * a great man fallen this day * * *?"

RESEARCH ON THE COMMON COLD

For several years prior to the discovery of the virus of influenza there was considerable interest in the etiology of the common cold. A number of important investigations were reported during that time, particularly by Dochez and his co-workers,^{1,2} in New York City and by Long and his collaborators³ in Baltimore. These studies were necessarily limited in scope and rather laborious, chiefly because of the failure to find a suitable experimental animal that is susceptible to the disease. To be sure, the chimpanzee was found to be susceptible, but that animal is difficult to handle and not readily available in adequate numbers. The use of human volunteers likewise seemed to entail so many difficulties that only a few investigations involving transmission to human subjects were reported. Some success was claimed with cultivation of a virus from the common cold and its propagation in tissue culture,⁴ but this was not confirmed by other workers. Meanwhile, the ease with which the viruses of influenza are isolated and manipulated has diverted the attention of many workers to studies with these agents, and a vast amount of information concerning influenzal infections has accumulated.

The recent war stimulated interest in a number of other human diseases that were of major importance and required immediate investigation. Researches on some of these diseases were also hampered by the failure to find suitable experimental animals. Under the impetus of the war, however, it was possible to obtain both funds and human volunteers to carry out fairly elaborate studies on the etiology and transmission of such diseases as infectious hepatitis and primary atypical pneumonia and on the therapeutic efficacy of certain chemical agents in human malaria. In this

country conscientious objectors and inmates of prisons were the main source of such volunteers. The feasibility of using human volunteers rekindled interest in the simple respiratory infections, particularly since the risks involved in acquiring such infections are much less than those that accompany experimental infections with the diseases just mentioned. At least three groups of workers have engaged in such studies on the common cold, and preliminary reports of the results of the work of two of these groups are now available.

Abernethy,⁵ of the Commission on Acute Respiratory Diseases, last year reported briefly on the successful transmission of minor respiratory illnesses to a group of human volunteers. He used filtered secretions from two patients who had different types of illness. The first had an incubation period of one or two days and was characterized chiefly by sneezing, nasal obstruction, coryza and cough, in the other, the incubation period was five or six days, sore throat was an outstanding feature, and nasal symptoms were minimal. These infections reproduced the same type of symptoms on transfer of filtered secretions to other volunteers in each instance. There appeared to be no cross immunity, and whereas a partial immunity to the homologous filtrate was demonstrated to the disease having the longer incubation period, no such immunity resulted from the illness with the short incubation period and the predominantly catarrhal symptoms. No illness resulted from inoculation of control filtrates obtained from the subject's own secretions. It was presumed that the agents that produced these two types of illness were filterable viruses.

A brief account of the plan of study and the nature of the work in progress at the Harvard Hospital in England has recently been given.⁶ This work was directed chiefly at attempts to cultivate and propagate the virus of the common cold in embryonated hen's eggs. It was calculated that there was about a 75 per cent chance of success with this method, because it had already proved successful in about three fourths of the attempts with sixty other viruses. Human volunteers were used to test the infectivity of the test materials. The source of the infective material was a pool of secretions obtained from twenty boys with colds

during an epidemic at Harrow, this had been stored at -76°C (in carbon dioxide snow).

The first results reported by the British workers indicate that the material retained its infectivity after at least four and a half months' storage at -76°C , for one month at -10°C and for three days in an ordinary refrigerator (4°C). The upper limit of the size of the infective agent was determined by passing it through graded filters, but the lower limit has not yet been defined. The incubation period of the disease produced was found to be two or three days in most subjects, but occasionally it was five or six days.

An interesting feature of the British studies is the source of the volunteers that were obtained. These were recruited at first among students during their holidays, but others readily became available as news of the work spread. The facilities were arranged to care for only twelve pairs of subjects at a time, different groups being started at intervals of two weeks. The success of the recruiting methods and the satisfaction of the volunteers with the way they were treated are attested by the fact that subjects are now booked for many months in advance. Moreover, many of the volunteers have expressed the desire to serve again and have been allowed to do so, but only after a lapse of six months.

Additional researches on the common cold are being carried out in this country by workers of the National Institute of Health under the direction of Dr Norman Topping.⁷ Some of the subjects of these studies are being recruited from inmates of a reformatory. These studies have only recently gotten under way.

All these investigations and others that may be in progress or that are being contemplated hold forth great promise for the solution, in the not too distant future, of many of the problems of the common cold, including its etiology, its epidemiology and perhaps even its treatment and prevention.

BUREAU OF CLINICAL INFORMATION

All secretaries of various medical groups, such as special societies and alumni associations, are requested to notify the Bureau of Clinical Information regarding scheduled meetings, annual dinners and so forth. If such data are on file, it is hoped that duplication of dates can be avoided.

DEATHS

KINLOCH—Raymond A Kinloch, M D, of Springfield, died on July 5. He was in his seventy-third year.

Dr Kinloch received his degree from University of Vermont College of Medicine in 1903. He was a member of the New England Obstetrical and Gynecological Society and a fellow of the American Medical Association.

His widow and a daughter survive.

PREBLE—Wallace Preble, M D, of Cambridge, died on February 22. He was in his ninetyeth year.

Dr Preble received his degree from Harvard Medical School in 1883.

A daughter survives.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

RELOCATION OF WASSERMANN LABORATORY

The Wassermann Laboratory of the Massachusetts Department of Public Health has been moved to the Bussey Building, 281 South Street, Jamaica Plain, Boston 30. The telephone number of the laboratory is ARNold 1232.

NEW APPOINTMENTS

William D Wellock, D M D, M P H, a Navy veteran and a recent graduate of the Harvard School of Public Health, has been appointed director of the Division of Dental Health. His private practice in Boston was interrupted by the outbreak of the war. As a commander in the United States Naval Dental Reserve, Dr Wellock served in the Alaskan Theater of Operations for more than two years. He received the degree of Master of Public Health from the Harvard School of Public Health following his separation from the Navy. Dr Wellock succeeds Dr A Laurence Corbman, who has heretofore served as acting director of the division.

Grace E Lutman, M D, M P H, Dr P H, a former assistant district state health officer in the

New York State Department of Health, has been appointed supervisor of Clinics for Crippled Children. Dr Lutman will administer the state clinics located in Salem, Brockton, Springfield, Fall River, Pittsfield, Lowell, Haverhill, Hyannis, Worcester, Greenfield and Gardner.

William W Wood, M B A, is serving as survey administrator in the Bureau of Hospital Survey and Construction. A Navy veteran, Mr Wood saw service in the Atlantic, Pacific, Mediterranean and Caribbean theaters.

Francis W Hooper, M D, has been appointed district health officer of the South Metropolitan District, with headquarters located in Quincy. Prior to his appointment, Dr Hooper saw eighteen months' service in the European Theater of Operations as a captain in the Army Medical Corps. He formerly practiced medicine in Westwood, Massachusetts.

MISCELLANY

NOTES

Dr Monroe Davis Eaton became associate professor of bacteriology and immunology at Harvard Medical School on July 1. Dr Eaton was born in Stockton, California, in 1904. He received his collegiate education at Stanford University, where he received an A B degree in 1927 and an A M degree in 1928. He graduated from Harvard Medical School in 1930, and for three years served as assistant in bacteriology and immunology in that school. Between 1933 and 1936 he was an instructor in bacteriology at Yale University School of Medicine, from 1936 to 1937 he was assistant professor of bacteriology and immunology at Washington University School of Medicine, and in 1937 he became a member of the staff of the International Health Division of the Rockefeller Foundation, as well as director of the Research Laboratory of the California State Department of Public Health.

Dr Donald G Anderson, until recently dean of the Boston University School of Medicine, has assumed the post of secretary of the Council on Medical Education and Hospitals of the American Medical Association.

CORRESPONDENCE

DANGERS OF POOLED PLASMA

To the Editor During the past year, four patients have died at our hospital because of severe liver disease following the infusion of "pooled plasma" at other institutions, and in all cases, the use of plasma had been ill advised. The indications for employing plasma are quite rare. If it must be used, it should be obtained from the blood of an individual donor who can be carefully checked for an antecedent history of jaundice or infectious hepatitis. That plasma is not a substitute for whole blood became obvious in the treatment of war casualties. That "pooled plasma" caused many deaths three to five months after the completion of brilliant surgery during the war years should militate against its use in civilian practice.

ALFRED HURWITZ, M D
Chief of Surgical Service

Veterans Administration Hospital
Newington 11, Connecticut

UNAUTHORIZED USE OF CORRESPONDENCE

To the Editor Recently, physicians in Boston, and possibly elsewhere, were circularized by a pharmaceutical house called the Chal-Yon Corporation. This corporation has launched a campaign advertising a product called Chal-Yon which,

among other things, is said to be effective against fungus infections. Included with a description of the therapeutic accomplishments of their product is a statement bearing my signature and dated August 2, 1946, to the effect that this material is nontoxic. The letter from which this statement was taken was addressed to an individual in response to his inquiries whether, in my opinion, the material was nontoxic.

In the statement that appears with the advertisement, my letterhead and signature are carefully reproduced but other parts are conveniently deleted. This abbreviated letter was distributed by the Chal-Yon Corporation, the existence of which I was entirely unaware (if, in fact, it did exist at all at the time) until the letter made its appearance in the mails. The effect of the letter is such that it appears to be a signed statement of indorsement not only by me but also by my associates, whose names appear on the letterhead.

I wish to inform those physicians who have received the circular that the use of this statement was entirely unauthorized. It was written to an individual and was in no way intended as an indorsement of the product recently advertised.

BOOK REVIEWS

Acetanilid. A critical bibliographic review. By Martin Gross M.D. With an introduction by Howard W. Haggard M.D. 8°, cloth, 155 pp., with 8 illustrations. New Haven, Connecticut: Hillhouse Press, 1946. \$3.00.

The appearance of many sensational articles in the press regarding certain generally used drugs—acetanilid for example—has led to considerable discussion some of it unscientific, and to controversial utterances by authorities concerning the difficulties and dangers in the use of this drug.

This book takes a step toward fact finding in the field of the intoxications, in which emotional attitudes and neglect of human factors have held sway in the past. Dr. Gross reviews the literature and includes a full length view of what acetanilid is and incidentally what it is not, described in terms of what acetanilid does and does not do. He does not minimize the difficulties in—and the necessity of—determining exactly how toxic acetanilid is—a matter that has been grossly obscured by uncritical alarmists in the past who have attributed to that drug alone the complicated end results of deficiency disease, chronic alcoholic addiction and various psychologic disorders that long antedated the invention of acetanilid. He points out its place in medicine, and outlines broadly its effectiveness as an analgesic.

This book does not contain a host of fresh facts. Rather it reinterprets many of the older and basic articles on acetanilid in the more recent light of psychologic and psychosomatic medicine. The best chapter deals with the question of addiction to acetanilid, a minor problem according to this author's figures. This chapter summarizes the whole problem of addiction and habituation in general as well as the particular aspects that apply to acetanilid.

Medical Education and the Changing Order. By Raymond B. Allen, M.D. Ph.D. Studies of the New York Academy of Medicine, Committee on Medicine and the Changing Order. 8°, cloth, 142 pp. New York: The Commonwealth Fund, 1946. \$1.50.

Dr. Allen is executive dean of the College of Dentistry, Medicine and Pharmacy of the University of Illinois. His monograph was prepared under the auspices of the Committee on Medicine and the Changing Order established by the New York Academy of Medicine and is one of a series each one of which is interesting.

The author presents a readable account of medical education describing first its historical background and later following the trends that have appeared to modify its course. His comments are shrewd and searching, he agrees with most medical educators that it appears difficult to attract to the study of medicine as high a type of student as is desirable because, in part, of the high cost in time and money. He gives many hints about medical education and how to make it more useful. He suggests, for example, that the curriculum

is not entirely perfect that pedagogic methods employed are not wholly adequate and that many internships—admittedly a vital part of a doctor's education—are not all they might be.

Dr. Allen concludes with a forecast the cost of medical education will not diminish there is no more crucial problem facing medical care than the distribution of doctors and that although in the past the services of medicine, like those of religion have been largely personal and although there will always be a need for personal services medicine of the future it is to progress as a social as well as a historic science, must broaden its outlook and adjust its educational program accordingly.

The Centennial of Surgical Anesthesia. An annotated catalogue of books and pamphlets bearing on the early history of surgical anesthesia. Compiled by John F. Fulton, M.D. and Madeline E. Stanton A.B. 8°, paper 102 pp. with 8 facsimiles and one portrait. New York: Henry Schuman 1946. \$4.00.

The compilers of this catalogue have assembled an excellent collection of literary material on the subject of surgical anesthesia. The period covered is from the time of Pliny and Dioscorides (A.D. 50 to 100) to the discovery of the use of ether in the United States in 1842-1846 and of chloroform in England in 1847 and to the rediscovery of nitrous oxide in 1853. The catalogue is divided into eight major divisions with a short historical introduction in each division, and the major items are annotated. The catalogue is limited to items exhibited at the Yale Medical Library in October 1946 either in the original or in facsimile. Naturally emphasis is placed on experimental work in the United States.

The first section concerns the forerunners of surgical anesthesia and includes the Greek and Roman authors and their references to mandragora and the soporific sponge, the use of physical agents, such as the snow and ice-cold water of Avicenna and Severinus and the method of nerve compression of James Moore (1784) nitrous oxide, carbon dioxide and the anesthetic agents, mesmerism and hypnotism and the early writings of Cordin (1561) and Turner (1743) on anesthetic ether. Subsequent sections are devoted to the American claimants of the discovery of surgical anesthesia Crawford W. Long, Horace Wells William T. G. Morton and Charles T. Jackson. Each lists in detail the original papers of the author, and title pages are reproduced in facsimile. The story of the controversy is presented in a factual manner without an endeavor to pass judgment on the merits of the matter. To each of these divisions is appended a list of references on bibliography and commentaries.

A large section which is concerned with the writings of and about Morton includes a census of the known copies of the Morton publications. (Since the publication of this catalogue the Boston Medical Library has acquired a copy of the rare third edition of Morton's fourteen-page *Lithicon* the earliest of this series to be located in any collection, public or private.)

Another section describes the discovery of chloroform and its use by Sir James Y. Simpson. During 1847 and 1848 the medical literature of the world became flooded with articles about ether anesthesia and in 1848 about chloroform. The seventh section comprises a list of references to publications of this period on ether, chloroform and other agents including opiates and nitrous oxide and mesmerism followed by a short list of early general monographs on surgical anesthesia and a note on anesthesia and psychiatry in which is described *The Anesthetic Revolution and the Gift of Phlebotomy* (1847) by Benjamin P. Blood. The concluding section comprises a long list of journal articles, monographs and addresses on the history of the subject.

The catalogue is printed and published in a deluxe manner and should be in all medical history collections.

The Diagnosis and Treatment of Bronchial Asthma. By Leslie W. Gay Ph.D. M.D. With a foreword by Warfield R. Longcope, M.D. 8°, cloth, 334 pp., with 80 illustrations. 5 plates and 39 tables. Baltimore: Williams and Wilkins Company 1946. \$5.00.

In recent years a number of encyclopedic books have been published on allergic diseases. Brief summaries are contained in systems of medicine. Dr. Gay has written a book

MASSACHUSETTS MEDICAL SOCIETY

BUREAU OF CLINICAL INFORMATION

All secretaries of various medical groups, such as special societies and alumni associations, are requested to notify the Bureau of Clinical Information regarding scheduled meetings, annual dinners and so forth. If such data are on file, it is hoped that duplication of dates can be avoided.

DEATHS

KINLOCH — Raymond A Kinloch, M D, of Springfield, died on July 5. He was in his seventy-third year.

Dr Kinloch received his degree from University of Vermont College of Medicine in 1903. He was a member of the New England Obstetrical and Gynecological Society and a fellow of the American Medical Association.

His widow and a daughter survive.

PREBLE — Wallace Preble, M D, of Cambridge, died on February 22. He was in his ninetieth year.

Dr Preble received his degree from Harvard Medical School in 1883.

A daughter survives.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

RELOCATION OF WASSERMANN LABORATORY

The Wassermann Laboratory of the Massachusetts Department of Public Health has been moved to the Bussey Building, 281 South Street, Jamaica Plain, Boston 30. The telephone number of the laboratory is ARNold 1232.

NEW APPOINTMENTS

William D Wellock, D M D, M P H, a Navy veteran and a recent graduate of the Harvard School of Public Health, has been appointed director of the Division of Dental Health. His private practice in Boston was interrupted by the outbreak of the war. As a commander in the United States Naval Dental Reserve, Dr Wellock served in the Alaskan Theater of Operations for more than two years. He received the degree of Master of Public Health from the Harvard School of Public Health following his separation from the Navy. Dr Wellock succeeds Dr A Laurence Corbman, who has heretofore served as acting director of the division.

Grace E Lutman, M D, M P H, Dr P H, a former assistant district state health officer in the

New York State Department of Health, has been appointed supervisor of Clinics for Crippled Children. Dr Lutman will administer the state clinics located in Salem, Brockton, Springfield, Fall River, Pittsfield, Lowell, Haverhill, Hyannis, Worcester, Greenfield and Gardner.

William W Wood, M B A, is serving as survey administrator in the Bureau of Hospital Survey and Construction. A Navy veteran, Mr Wood saw service in the Atlantic, Pacific, Mediterranean and Caribbean theaters.

Francis W Hooper, M D, has been appointed district health officer of the South Metropolitan District, with headquarters located in Quincy. Prior to his appointment, Dr Hooper saw eighteen months' service in the European Theater of Operations as a captain in the Army Medical Corps. He formerly practiced medicine in Westwood, Massachusetts.

MISCELLANY

NOTES

Dr Monroe Davis Eaton became associate professor of bacteriology and immunology at Harvard Medical School on July 1. Dr Eaton was born in Stockton, California, in 1904. He received his collegiate education at Stanford University, where he received an A B degree in 1927 and an A M degree in 1928. He graduated from Harvard Medical School in 1930, and for three years served as assistant in bacteriology and immunology in that school. Between 1933 and 1936 he was an instructor in bacteriology at Yale University School of Medicine, from 1936 to 1937 he was assistant professor of bacteriology and immunology at Washington University School of Medicine, and in 1937 he became a member of the staff of the International Health Division of the Rockefeller Foundation, as well as director of the Research Laboratory of the California State Department of Public Health.

Dr Donald G Anderson, until recently dean of the Boston University School of Medicine, has assumed the post of secretary of the Council on Medical Education and Hospitals of the American Medical Association.

CORRESPONDENCE

DANGERS OF POOLED PLASMA

To the Editor During the past year, four patients have died at our hospital because of severe liver disease following the infusion of "pooled plasma" at other institutions, and in all cases, the use of plasma had been ill advised. The indications for employing plasma are quite rare. If it must be used, it should be obtained from the blood of an individual donor who can be carefully checked for an antecedent history of jaundice or infectious hepatitis. That plasma is not a substitute for whole blood became obvious in the treatment of war casualties. That "pooled plasma" caused many deaths three to five months after the completion of brilliant surgery during the war years should militate against its use in civilian practice.

SOME OBSERVATIONS ON TRANSURETHRAL PROSTATIC RESECTION*

REED M. NESBIT, M.D.†

ANN ARBOR, MICHIGAN

WHEN resident surgeons are taught the performance of transurethral prostatic resection at the University of Michigan Hospital and when matters pertaining to resection are discussed with visiting urologists, it has appeared desirable to emphasize certain details of technic that have been found necessary to the successful execution of operation. Many of these appear not to have been adequately elaborated on in the literature, and for that reason it seems appropriate to report some of the particulars that are considered to be fundamental.

The earliest description of operative procedures, purposefully designed to relieve obstructive uropathy, was written by Ambroise Paré, who, in the sixteenth century, recognized the existence of lesions that he termed "carcinosis" and removed with instruments of his own design. Paré's instruments were introduced through the urethra and effected the removal of the obstructing tissue by a scraping or "shearing" maneuver. It is probable that the lesions described by Paré were urethral strictures, for they appear to have been located in the urethra and their presence was antedated by a purulent discharge.

Prostatism was first recognized at the beginning of the nineteenth century, and all the earliest approaches to the relief of the disease were made via the urethral route. The surgeons of that day were adept at the division of strictures and were experts at crushing vesical calculi, and it was therefore natural that they should improvise on their familiar technics in the treatment of the newly discovered disease, rather than develop new and revolutionary procedures.

The ingenuity that was exercised by our urologic predecessors of this period was most interesting and attested to their great skill, as well as to the urgency of the problem that confronted them. The direct surgical attack on the prostate gland was delayed until the Listerian era, when surgical versatility became possible.

*Presented at a meeting of the New England Section of the American Urological Association, Boston, November 14, 1946.

†From the Department of Surgery, University of Michigan Medical School.

†Professor of urology, University of Michigan Medical School.

All the early intraurethral operations failed of their purpose, since none of them cured prostatism because they did not effect the removal of obstructing tissue. This was first successfully accomplished when methods of enucleation were discovered, and until the modern resectoscope was invented, surgeons were required to perform open operations to extirpate the abnormal prostate. Now the diseased gland can be removed safely through the urethra, and many of the well recognized hazards, as well as inconveniences, of open prostatectomy may thus be eliminated.

The resectoscope of today is a product of modern inventive genius. It owes its existence to three fundamental discoveries: the incandescent light, the high-frequency current and the fenestrated sheath. With this device the surgeon is able to excise tissue rapidly and with a minimum of tissue destruction; he is able, at all times, to orient himself perfectly within the field of operation and, with the help of the magnifying-lens system employed in modern instruments, to identify more accurately than with the unaided eye all structures within the field of operation. Bleeding is under complete control, and by employing instruments that can be operated completely with one hand, the surgeon is able to use his free hand for rectal palpation, which provides him with tactile, as well as visual, guidance during operation.

Most urologists have employed this method in treating urinary obstructions. Some have found only a limited scope of usefulness for the procedure, whereas others have perfected technics that have enabled them successfully to employ resection exclusively in the treatment of all obstructions at the bladder neck. Our position at the University of Michigan Hospital has been somewhere between the two extremes. We have made continuous efforts to explore objectively the ultimate possibilities of the method, but meanwhile have endeavored to maintain a balance of technical advance in the other types of prostatectomy consonant with our responsibilities in the training of well rounded resident surgeons.

The first patient on whom transurethral prostatic resection was performed in the University of Michigan Hospital in October, 1931, enjoyed a comfortable and uncomplicated convalescence and left the hospital a few days after operation proclaiming widely the miracle that he considered had been performed on him. His basis for opinion in the matter was extremely limited, consisting only of a comparison of his hospital experience with that of all the other patients on the ward, who were convalescing from suprapubic and perineal prostatectomies. But our own experience in the matter was equally limited, so that our immediate enthusiasm was perhaps not entirely unjustified. A less spectacular result in the first case would doubtless have resulted in a more conservative appreciation of the operation's potentialities, for during the years that followed it was constantly hoped that each successive patient would enjoy the beneficent results that the first patient had derived. The naïveté of this attitude probably explains why subsequent failures and disasters did not arouse a feeling of condemnation for the operation, but rather stimulated critical evaluation of its performance. Experience has shown that prostatic resection possesses many attendant hazards and that there are numerous pitfalls in the performance of this technically difficult operation. Most of these can be considered under the headings of trauma and hemorrhage.

Trauma

One of the most frequent causes of both immediate and late complications after resection is urethral trauma, for the standard resectoscope has a large, rigid sheath, and all urethras do not readily accommodate it. When the urethra is traumatized by forceful introduction of instruments that are too large, or insulted by a snugly fitting sheath in the urethra during a long operation, certain grave sequelae are inevitable. The introduction of infection, which is likely to occur as an immediate complication, is manifested by the development of local tenderness of the urethra and general sepsis, later, the development of stricture completes the cycle and may leave the patient with a lesion that is just as debilitating and infinitely more difficult to treat than prostatism. Urethral trauma is usually avoided if the surgeon is careful not to introduce the standard-size resectoscope into a urethra that fails to accommodate easily a No. 30 Fr. steel sound. When smaller urethras are encountered, alternative technics can be employed. One consists of the use of a resectoscope having a sheath of smaller than standard diameter.

At present a McCarthy instrument with a sheath diameter of No. 24 Fr. is available, and it is hoped that in the near future instruments will be constructed so that one working element can be employed with various loops and sheaths in sizes No. 24, 26 and 29 Fr. If the use of smaller instru-

ments is impractical or impossible, the surgeon has two procedures that can be followed. Meatotomy will often permit the unimpeded passage of the resectoscope, but in some cases the remainder of the urethra is too small after the meatus has been enlarged. Perineal urethrotomy is then indicated. About 35 per cent of the patients operated on by resection in the University of Michigan Hospital require meatotomy, whereas perineal urethrotomy is performed in 20 per cent.

Other indications for perineal urethrotomy include severe urethritis, shortness of the penile suspensory ligament, excessive length of the prostatic urethra and abnormal position of the prostate gland. When a short suspensory ligament is present the curvature of the anterior urethra is exaggerated and causes resistance to the passage of straight instruments. The urethra may be traumatized at the penoscrotal angle, where maximum tension occurs, or the end of the sheath may be thrust downward into the prostatic bed during operation in such a way as to create damage. On one occasion I experienced this disaster while operating on an obese and emphysematous subject. The prostate gland was not large, and the operation was brief. The suspensory ligament was short and caused the resectoscope to be held rigidly in the urethra. Perineal urethrotomy seemed indicated, but was not performed, for it was decided that the small resection could be finished in a few minutes. When the operation had been completed and a catheter introduced, there was an abnormal amount of bleeding, so that the instrument was reintroduced for the purpose of arresting it. While this was being done, the patient coughed violently, and the force thus created caused the resectoscopic sheath to penetrate through the floor of the prostatic capsule. He later died of pelvic cellulitis. This tragedy would not have occurred if the resectoscope had been contained lightly in the urethra, for the force exerted by the cough would easily have moved the instrument rather than causing the patient to be impaled on it.

In some cases in which the prostatic urethra is long or the prostate gland is situated high in the pelvis, the resectionist is required to exert pressure on the instrument to insert it far enough to be in a proper position for operation. The employment of even this small amount of force in the handling of the resectoscope can be avoided if perineal urethrotomy is utilized. In performing resection on large glands—that is, those in which 50 gm. or more of tissue is removed—we have employed urethrotomy in 30 per cent of cases, in comparison to 20 per cent for all cases. In the resection of large glands the procedure has allowed an increased maneuverability that has facilitated the technic of operation.

It can be accepted as an axiom of transurethral prostatic surgery that the resectoscope must be freely and easily contained by the urethra at all

times The instrument that is held tightly in the urethra under any circumstances cannot be maneuvered successfully or safely by the surgeon in the performance of an operation that requires delicate and precise dissection The single exception to this rule is when the instrument is held tightly in the prostatic urethra by cancer or by a vesical-neck contracture Whenever perineal urethrotomy is indicated to effect this purpose, it should be done, for it is simple to perform and patients suffer little or no inconvenience from it. They rarely pass urine through the incision, and none develop stricture at the site of operation

Another form of traumatic injury occurs when the resectionist cuts too deeply into vulnerable areas The most frequent are perforation of the prostatic capsule and injury of the external urinary sphincter Minor perforations of the prostatic capsule often occur in the performance of transurethral resection by surgeons who attempt a subtotal removal of the gland These minor perforations rarely give rise to morbidity and are probably of little clinical significance—a circumstance that on certain occasions has permitted me deliberately to excise a small portion of the capsule with the resectoscope, either for the purpose of biopsy or to demonstrate to a visiting urologist that the structure in question was actually the prostatic capsule When small perforations occur the healing of the defect probably takes place quite rapidly and is enhanced by the catheter diversion of the urine. Extensive perforation may give rise to pelvic cellulitis and extravasation, and if not recognized and promptly treated by adequate drainage, will terminate fatally The average resectionist, however, is adequately oriented at all times and is able to recognize any perforations of the capsule that occur If the perforation is extensive, he can perform immediate suprapubic drainage, if it is small or of dubious size, he can remain on the alert for the development of unfavorable symptoms

Urinary incontinence following transurethral resection is much like the weather—a great deal has been said, but little done about it. It occurs when the external sphincter is cut with the resectoscope—an accident of technic that can easily be avoided in the hands of the average resectionist This complication has occurred in only 3 cases in the University of Michigan Hospital series, and in view of the fact that nearly half the operations were performed by various members of the resident staff, it is at once evident that it can be avoided by even the inexperienced resectionist if due care is exercised in the performance of a sound technic Except in the presence of infiltrating cancer or inflammatory contracture that involves the membranous urethra, the proximal margin of the external sphincter can be recognized with the fore-oblique-lens system, which affords perfect illumination and great magnification of the tissues in the field of vision Recognition of the upper sphincter margin is made

possible by certain anatomic properties of the structures that go to make up the area These structures have been described as follows

The fixed portion of the urethra includes the prostatic and the membranous portions the membranous urethra is the only part that has practically no mobility The prostatic portion may be moved slightly within the limits allowed by the pubo-prostatic ligaments and by the connection of its capsule with the superior layer of the triangular ligament in front and the recto-vesical fascia and rectum beneath and above.

Thus, anatomically, the membranous urethra is an immobile structure, whereas the adjoining prostatic urethra is slightly movable, but the mucosa of each structure is tightly adherent. When the prostate gland is moved, the surface configuration at the prostatomembranous junction is altered by wrinkling in a manner comparable to the wrinkling of the bellows that connects two Pullman cars The mucosal folds that are created in this manner are transversely disposed and extend around the entire circumference of the urethra They can be recognized easily when observed through the resectoscope, and are brought into view most effectively if the instrument is moved in and out through a short excursion while the area is being inspected Fortunately, this wrinkling phenomenon tends to increase as transurethral resection progresses because of the increased mobility of the gland that is effected by the operation, so that the surgeon can always demonstrate the prostatomembranous junction toward the end of the operation and can safely excise tissue down to that point without fear of sphincter injury

Hemorrhage

Every prostatic resection is accompanied by blood loss Often, the amount is negligible, but it may be considerable and can materially influence the morbidity and mortality It is important, therefore, that the resectionist have more or less accurate information regarding the amount of blood loss, rather than relying on impressions gained during the performance of operation, for significant losses can occur and escape notice while he is concentrating his attention on the details of operative technic.

A simple method that can be employed for the estimation of blood losses after resection was described by Nesbit and Conger² in 1941 This procedure takes only two or three minutes and provides the surgeon immediately with objective data regarding the patient's need for replacement therapy When resection is undertaken in feeble and debilitated patients or those with extremely large prostates it is often advisable to start the administration of blood at the beginning of operation

The successful control of bleeding during operation depends a good deal on certain details of technic that are generally acquired with experience Bleeders are quite easily recognized and can be quickly arrested when the walls of the prostatic fossa are

smooth and clean, for then the resectionist is able rapidly to survey the entire operative field from a vantage point at the membranous urethra. But when the operative field has an irregular and uneven surface, bleeding points are not readily seen from such a panoramic survey, finding them often requires a long and painstaking search, and the roughness of the irregular surface tends to increase the difficulties in question by enhancing the formation of blood clots, which in turn conceal under-

each excursion of the cutting loop extend the full length of the adenomatous mass that is being resected. When long masses of tissue are to be excised the operator, while cutting, may slide the sheath of the instrument toward himself with the loop extended, so that longer slices of tissue than would otherwise be permitted by the full excursion of the loop can be excised. One can frequently remove pieces of tissue that are 5 cm or more in length by sliding the resectoscope during the cut-

FIGURE 1 Plaster Moulage Indicating the Manner in Which a Lateral Lobe of the Prostate Is Dissected Out

In this case, with the left lateral lobe (P) involved, the resection is started near the top of the lobe and is deepened laterally and downward to dissect the lobe away from the prostatic capsule (C)

lying bleeders. Our resident surgeons who are beginning to learn the operation often have considerable difficulty in finding bleeders. When their more experienced preceptors take over, they usually encounter a field of operation resembling plowed ground, in which bleeding points are most difficult to identify. To clarify the situation, it is necessary to eliminate the peaks and furrows by long, continuous sweeps with the cutting loop. After the walls of the fossa have been leveled off, little difficulty is encountered in finding and stopping bleeders. The experienced resectionist strives to make

the process. In employing this technic, however, the surgeon should always remember that the tissue that is being traversed must be kept under direct vision at all times, and that every landmark must be visible while the instrument is in motion. When the distal end of the adenomatous mass comes into view, the movement of the sheath is stopped, and the cutting loop is pulled forward and finally appears within the sheath shearing off the fragment. The instrument is then kept in place while the tissue fragment floats away in the stream of water flowing through the sheath, permitting an unimpeded view

of the excavation, and the operator can either arrest bleeding within the excavation or continue to carry out his cutting maneuvers. By a technic of this sort, the cut surface can be kept smooth and free from bleeding points and blood clots during operation.

The injection of various vasoconstrictive substances into the prostate gland to lessen the amount of bleeding during operation has been advocated by some authors. When these substances are injected, the bleeding is often reduced to a remarkable extent. In fact, some of the glands do not bleed at all during resection. But when the vasoconstriction dis-

operative irrigations of the bladder. After the O'Connor technic had been employed with great success—and incidentally with the elimination of a vast number of hours of nursing—a question was raised regarding the reason for success of the method, since the O'Connor technic had brought about two distinct changes in the routine of postoperative care: the employment of thrombin and the elimination of irrigations.

To determine which factor was responsible for the success of the method, two series of cases were observed. In one, thrombin was used, and in the other it was omitted, but in both series no irrigations were

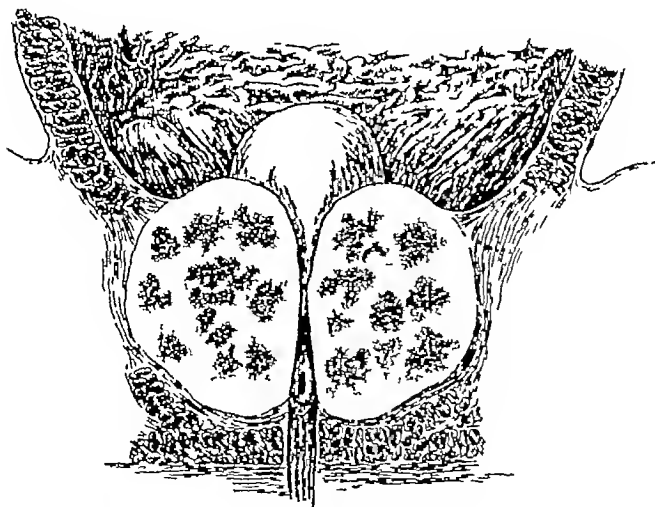

FIGURE 2. Diagram Showing Obstruction at the Bladder Outlet Produced by Hypertrophy of the Two Lateral Lobes and the Median Lobe of the Prostate

appears, a subsequent vasodilation occurs and some of the patients bleed excessively. None of the methods of injection that have been proposed thus far are to be recommended.

The postoperative control of bleeding is another problem that concerns the resectionist. Formerly, it was our practice routinely to irrigate the bladder with water every ten or fifteen minutes during the first twenty-four hours after operation. This was done in an effort to prevent excessive bleeding and to ensure against blockage of the catheter with blood clots. Some resectionists employ continuous irrigation for the same purpose. About two years ago, Dr Vincent O'Connor² described a method of controlling postoperative bleeding by instilling thrombin into the prostatic fossa via the catheter following resection. For the thrombin to effect hemostasis it was necessary to eliminate all post-

carried out. Determinations of postoperative blood loss were made in all cases, and the amounts were the same in both series. The results of these studies have been reported in a publication by Ratliff and Plumb.⁴ We now employ no thrombin and do not irrigate after resection. There have been fewer cases of catheter blockage than ever before, and the nursing department is delighted to have been relieved of the incessant and onerous duty that was previously its lot.

Operative Technic

A short resume of a technic that has been successfully employed in prostatic resection is presented. In this procedure there are three phases of operation: in the first a cone of tissue is removed—the apex of the cone is at the apex of the prostate, and the base of the cone is encircled by the internal

vesical sphincter, the second phase consists of removal of the remaining lateral-lobe structures from within the concave prostatic fossa, and the third phase is concerned with a careful removal of the apex masses of tissue abutting on the external sphincter. In the first phase of operation the resectoscope is

end of the lobe just lateral to the commissure and is drawn forward along with the resectoscope, and a fragment of tissue extending the full length of the lateral lobe mass is excised and allowed to float into the bladder. The surgeon immediately inspects the furrow that remains, coagulates any bleeding points

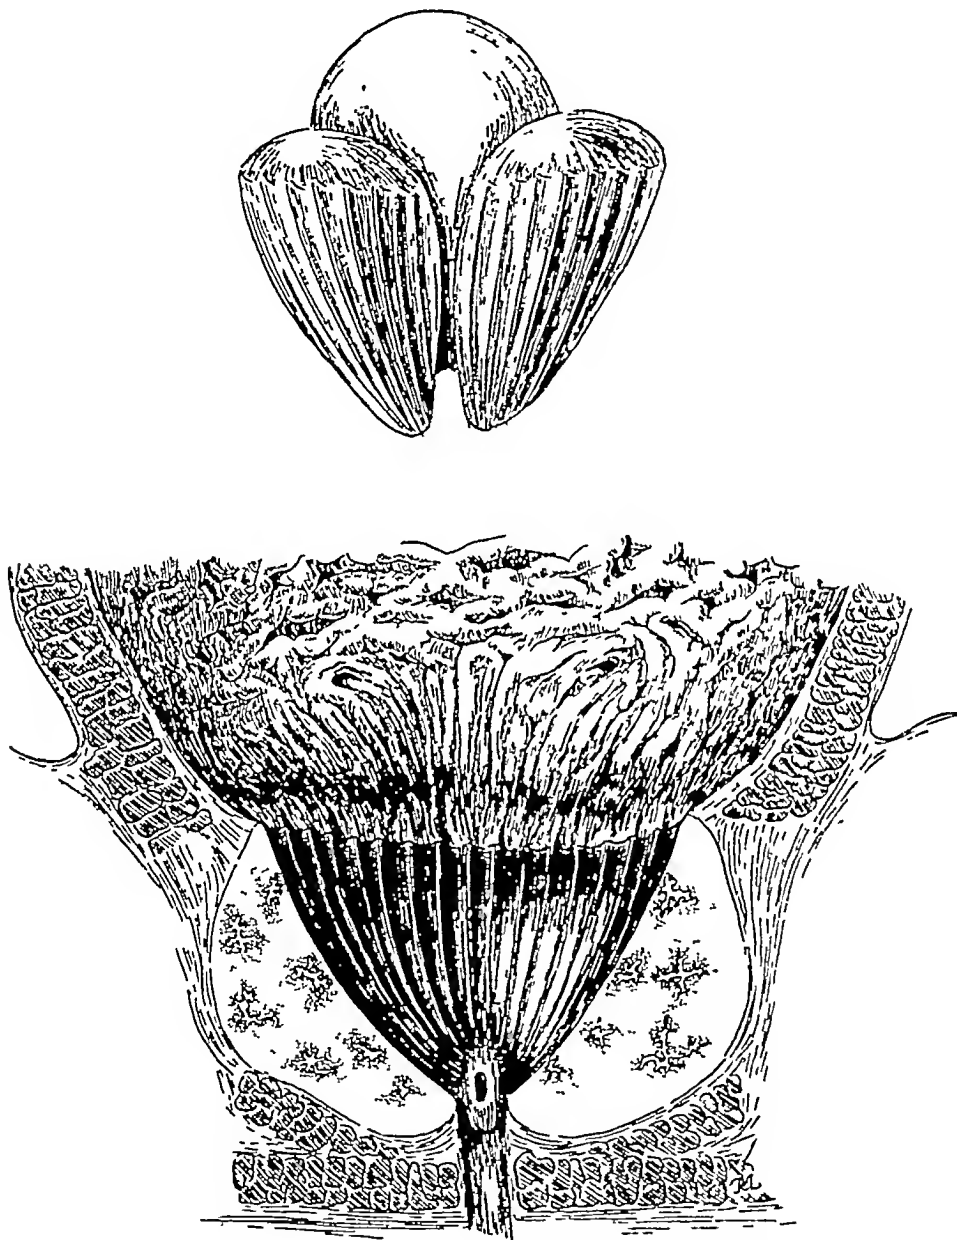

FIGURE 3 Diagram Showing the Cone-Shaped Area Left after the First Phase of the Operation Has Been Completed

Although a large part of the median and lateral lobes has been removed, there still remains much prostatic tissue to be removed from the concave prostatic fossa

rotated so as to enable inspection of the anterior wall of the prostatic urethra. The anterior commissure is observed, and one of the lateral-lobe masses is often found to bulge more prominently than the other into the field of vision. This one is chosen for the beginning of the operation. The extended cutting loop is brought into contact with the cephalad

and carefully inspects the morphology of the tissues that have been laid bare.

The observation of tissue morphology during operation is of primary importance, for it is only in this manner that the surgeon is guided in determining what should not be excised. The tissues of the adenomatous mass have a characteristic appear-

ance that varies only when there is an excessive leiomyomatous stroma. The appearance of the compression capsule is different from that of either the normal or the adenomatous prostate gland, it has a sort of asbestos appearance when viewed through the foreoblique-lens system. Infiltrating cancer is identified by its cellularity. The internal sphincter is easily recognized by its circular muscle fibers, and the prostatic capsule has a fibrous appearance that facilitates identification.

During resection, if only prostatic tissue is identified in the initial furrow, another fragment of

apex of the prostate converge at a point, for the membranous urethra is a fixed point. Thus, the confluent furrows that successively expose the circumference of the internal sphincter create a cleft extending from that circle out to the apex, and the cleft that is created in the manner described often encircles sizable masses of prostate (Fig 1). These masses are composed of portions of the lateral lobes and of the median lobe, and when encircled as described and cut off from peripheral circulation, the entire mass can be cut up into fragments quickly and bloodlessly. In the resection of small obstructing

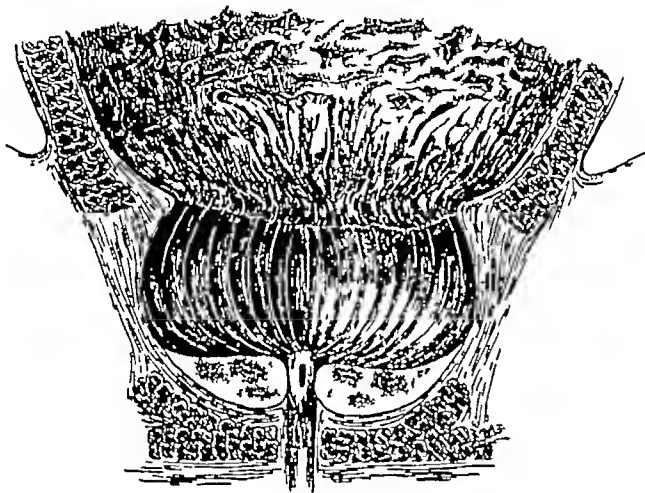

FIGURE 4 Diagram Showing How the Prostatic Tissue Is Removed from the Concave Fossa down to the Capsule of Prostate

At the conclusion of this second phase of the operation, there remains only some prostatic tissue at the apex of the gland adjacent to and just above the external voluntary sphincter muscle. In the third stage of the operation this remaining tissue at the apex of the prostate gland is removed.

tissue can safely be excised in the same line, but if muscular fibers are recognized at the inner end of the furrow, the operator must cut no deeper at that point. Instead, the resectoscope is rotated a few degrees laterally so as to begin its next excision of a tissue fragment. This slice of tissue and each successive one extend, like the first fragment, the full length of the prostate gland, and the furrow that is formed by the second cutting stroke is confluent with the first, and, like the first furrow, is deepened until the circular fibers of the internal sphincter are encountered, then the resectoscope is again rotated a few degrees, and another adjoining furrow is made. It is noteworthy that each of the successive cuts exposes a small arc of the internal sphincter but that the individual furrows extending toward the

glands or contractures, the cutting maneuvers in the first zone of operation often entail only the removal of a shallow depth of tissue, so that there may be no encirclement of a tissue mass. When the first phase of operation has been concluded, there is a cone-shaped space extending from the apex of the gland to the circle described by the internal vesical sphincter. The walls of this cone are smooth and are composed of prostatic tissue, and any bleeding points are easy to identify (Fig 2 and 3).

The second phase of the operation is concerned with the removal of adenomatous tissue from the concave prostatic fossa. In this zone the cutting loop enters the prostatic mass distal to the circular fibers of the internal sphincter, and each excursion

of the loop extends almost to the external sphincter, where a small mass of tissue is allowed to remain as a bulwark against injury of the sphincter. In this subvesical zone the first cut is made anteriorly, and successive cuts are made in the same furrow until the capsular structures are recognized. Successive cuts are made lateral to the original furrow until capsular structures come into view, and dissection is continued with the object of creating a cleft that is peripheral to the adenomatous mass of tissue. Digital palpation of the prostate gland during the resection within the posterior half of the fossa is essential to accurate and safe dissection, for with a finger in the rectum the surgeon is able to palpate quite accurately the thickness of the adenoma and, when nodular masses are relatively inaccessible because of unusual position, to push them upward into the path of the cutting loop. This maneuver is particularly valuable in the excision of tissue masses situated just beneath the internal sphincter, either in the midline or laterally, where significant masses are often encountered. I have often found it necessary to excise masses of tissue at least 2 cm in diameter that were situated beneath the apex of the trigone. In such cases resection of the adenoma down to the thinned-out capsule could be performed with safety only by accurate palpation, and often these masses of tissue are excised most effectively when they have been pushed upward forcibly by the finger in the rectum. By peripheral dissections in the second zone of operation, the adenomatous mass is devascularized so that the free mass that is finally isolated on the floor of the urethra can be expeditiously and safely excised by rapid resection.

At the conclusion of the second phase of operation, the surgeon is able to survey the entire fossa from a vantage point at the apex of the gland. In the distance he can see the denuded internal sphincter, and in the foreground he is able, by rotating the instrument, to inspect the smooth, concave walls of the prostatic fossa. Bleeding points are readily discovered (Fig 4).

The final phase of operation requires a meticulous and careful dissection, for it is now that the surgeon resects all tissues down to the margin of the external sphincter. This margin is readily identified, as described above, by observation of the transverse fold or wrinkle that is made visible when the resectoscope is moved out and in and rotated while the area in question is inspected. When the outer margin of safe resection has thus been delineated throughout its entire circumference, the excision of apical tissue can be carried out as far as this line. A convenient place to start resection of tissue in this zone is anteriorly, the instrument is then rotated as successive adjoining fragments of the gland are excised until the ejaculatory ducts and the verumontanum are reached, but these structures are not removed. The surgeon must bear in mind that, although the

apex of the adenomatous gland is tapered in form and ends at the triangular ligament, it often extends laterally for some distance on this abutment, and resection at the apex must extend not only down to the urethral level but also deeper on each side of the midline so as to include the removal of all adenomatous tissue contained within the capsule. This is greatly facilitated by rectal palpation during operation. Failure to extirpate the entire apex mass often results in post-resection difficulties, for the remaining tissues expand and project into the urethra and may produce irritation or obstruction.

By employing a systematic approach in the technic of transurethral resection the urologist is enabled to perform a subtotal removal of the prostate gland, and the size of the gland that is removed depends in a large measure on the factors of dexterity and experience in the performance of this operation. Most experienced surgeons today believe that subtotal prostatectomy is essential to the attainment of consistent good results, and when this objective cannot be attained the urologist will be well advised to treat his patient by some enucleative procedure, for the cure of prostatism today, as in Freyer's day, depends on the extirpation of the gland.

* * *

The present report is not concerned with any evaluation of transurethral prostatic resection. To do so would inevitably introduce matters relating to opinion, and debate has never settled the fate of any therapeutic method. Time will eventually determine the ultimate place of transurethral resection in the surgery of the prostate gland.

In conclusion, the following paragraph from a treatise by Deaver⁵ is regarded as pertinent.

Whether or not every shred of prostatic substance is removed by Freyer's operation is of very little consequence, who first performed such an operation is of less and whether it is anatomically possible or not is of no consequence at all, since the results in Mr Freyer's case speak for themselves, and he has aroused the profession not only in his own country but in France and America as well, to the realization of what a brilliant chapter of prostatic surgery is unrolled in his achievements. Indeed were I inclined to criticize the reports of Mr Freyer's case in any way, it would be to say that they were almost too good to be believed, except when coming from such a source, so much like a fairy story do they read.

THE EXAMINATION OF SEROUS FLUIDS BY THE CELL-BLOCK TECHNIC*

C B CHAPMAN, M.D.,† AND E J WHALEN, M.D.†

BOSTON

THAT serous fluids from patients suspected of having malignant tumors may yield information of considerable diagnostic value has been established for many years, and in 1917 Mandelbaum¹ devised a technic for the preparation of cell

has been a steady increase in the number of specimens of serous fluids submitted for examination, and for the past five years, between 150 and 200 specimens have been examined each year. We were led to review the material not only because of the num-

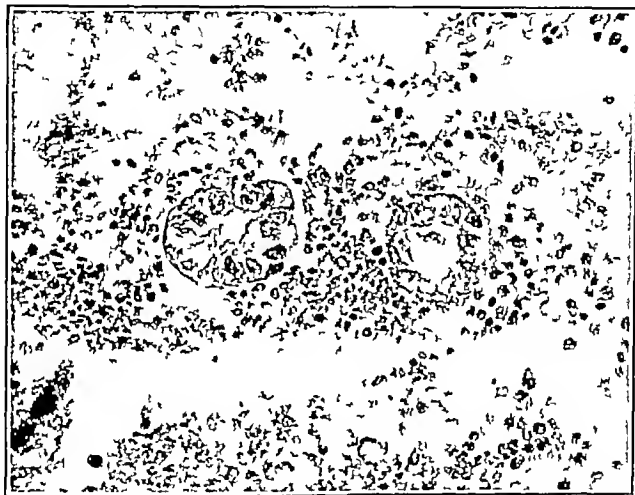

FIGURE 1 Acini in Sediment from Pleural Effusion Produced by Seeding of Adenocarcinoma of Breast to Pleura (x520)

There is moderate anaplasia of the cells composing the acini

blocks that, with but few modifications, is generally employed at present.

Evaluations of the procedure as employed in various laboratories have been published by a number of workers, including Zemansky,² Schlesinger³ and Honigman,⁴ all of whom showed conclusively that, when properly carried out, the method is not only technically practical but also diagnostically useful. Zemansky has traced in some detail the development of the method, and reference should be made to his paper for information of this type.

We cannot ascertain when the first cell block was prepared and examined at the Mallory Institute, but the records show that before 1931 the technic was employed infrequently. Since that time there

has been a steady increase in the number of examinations available but also because clinicians and pathologists alike often express discouragement at the apparently small number of positive results obtained by the use of the technic.

METHOD

The method that has been in use at the Mallory Institute during the fifteen and a half years covered by this survey is similar to that devised by Mandelbaum, with a few modifications. At present we employ the following procedure:

The fluid sent for examination is allowed to settle overnight in the refrigerator. The supernatant fluid is then decanted, and the cloudy or clotted residual is centrifuged in a tapered 50-cc. tube for thirty minutes at 3000 r p m.

*From the Mallory Institute of Pathology, Boston City Hospital.
†Intern in pathology, Mallory Institute of Pathology.

After centrifuging, the supernatant fluid in the tube is poured off, and Zenker's fluid added. The block is fixed in the tube for twelve hours.

The fixed block is dislodged from the tube by gentle pressure at one edge with a wire loop or the blade of a forceps.

The entire block is placed on its side on filter paper and is sectioned in the usual manner. Stain-

as usual, and 50 or 100 cc is then taken from the bottom of the container. To this portion 10 cc of Zenker's fluid is added to precipitate the protein and to fix the cells in the fluid. This is then centrifuged and prepared in the usual manner.

For a positive diagnosis on a cell-block preparation the following characteristics are required: the presence of fully or partly formed acini or of solid

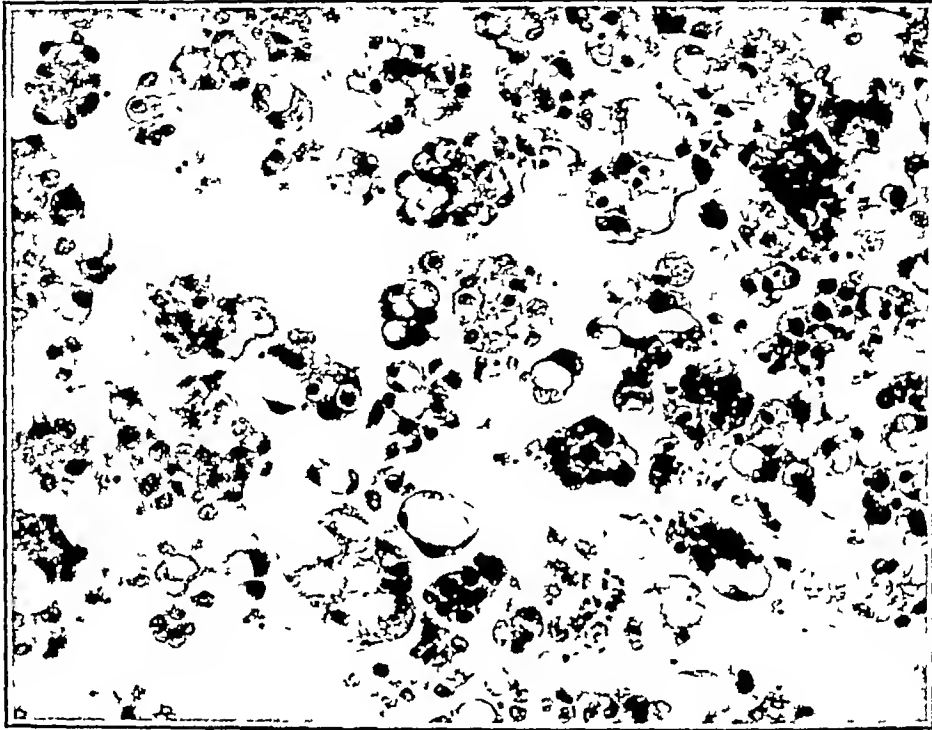

FIGURE 2 *Clumps and Crude Acini from Ascitic Fluid in a Case of Adenocarcinoma of Undetermined Origin (x260)*

Marked anaplasia and the presence of many signet forms are striking features

ing is carried out as for any pathological specimen, the routine stain in this laboratory being phloxine and methylene blue.

When overnight sedimentation fails to produce a cloudy layer at the bottom of the container, we have occasionally resorted to Schlesinger's³ technic of centrifuging the specimen, 50 cc at a time, pouring off the supernatant fluid and adding a fresh quantity to the same tube until the entire specimen has been centrifuged. If the fluid is too acellular to yield a good block by centrifuging alone, we employ a modification of a technic attributed by Henderson and Muirhead⁵ to Alzheimer and originally devised for the examination of cells in spinal fluid. The method depends on the precipitation of a protein coagulum to ensnare cells suspended in the fluid. Most serous fluids contain enough protein to yield a voluminous precipitate on addition of a precipitant such as 10 per cent formalin or Zenker's fluid. The specimen is allowed to settle overnight

sheets of cells, and evidence of anaplasia in the cells composing the formation—this includes pronounced variation in nuclear staining, eccentric position of nuclei and irregularity of cytoplasmic outlines. The presence or absence of typical or atypical mitotic figures is regarded as a secondary consideration.

RESULTS

The records of the laboratory show that from January 1, 1931, to June 30, 1946, a total of 1078 specimens of serous fluids were submitted. Of this number, 245 were reported as yielding insufficient sediment, leaving 833 specimens actually examined. Since multiple examinations were not infrequently carried out on the same patient, the latter figure actually represents 666 patients. Qualified or unqualified diagnoses of neoplastic disease were made on one or more specimens from 102 of the 666 patients (15 per cent). C

* owing malignancy

nant neoplasm at autopsy or by biopsy, cell-block preparations were positive in 47 (41 per cent)

The process apparently responsible for serous effusions was found at autopsy or biopsy in 163 cases (Table 1). The types of malignant neoplasm found in this group are presented in Table 2

DISCUSSION

The usefulness of the cell-block technic is considered to be well demonstrated by the fact that

are the care with which the cell blocks are prepared and the criteria employed in evaluating the cells found. In our relatively large series the interest in the procedure and the methods employed in the preparation of cell blocks have fluctuated from time to time. Similarly, the diagnostic criteria in use have not been constant for the entire time. Early in the period covered by this survey positive diagnoses were occasionally made on the basis of single cells, along the lines suggested by Graham⁸

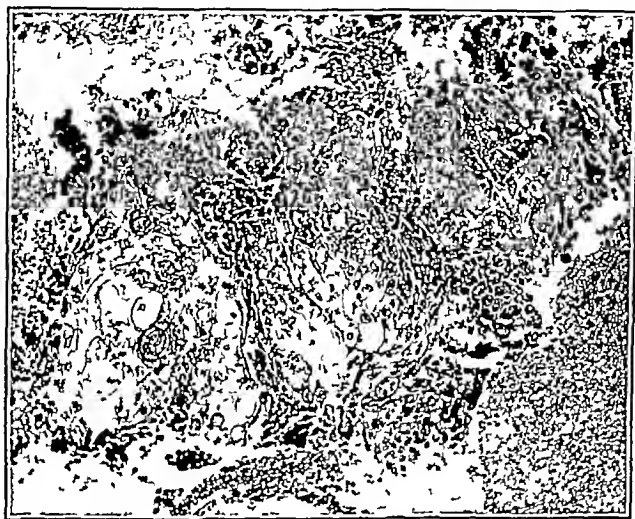

FIGURE 3 Portion of Tumor from Pleural Fluid in a Case of Epidermoid Carcinoma of Undetermined Origin (x160)

drawn and submitted for examination. In Zeman-sky's² series of 730 cases positive diagnoses on the basis of examinations of cell blocks were returned in 156 cases (21 per cent). The comparable figure in the Honigsmann⁴ study was 29 per cent, and in that of Schlesinger⁵ was 35 per cent.

Probably the most important factors in determining the proportion of positive results obtained

More recently, there has been a tendency to increasingly conservative diagnostic standards so that at present fully formed acini and evidence of neoplastic growth in the form of individual cells are often required (Fig 1). In our opinion these criteria may safely be relaxed in certain particulars. We agree that definite cellular arrangement is essential, but a demand for complete acini is regarded as limiting the usefulness of the method. Some malignant tumors—for example, epidermoid or medullary carcinomas—may release cells that show no true acinar arrangement but are identifiable as malignant by virtue of the highly atypical cells making up the sheets (Figs 2, 3 and 4). Even in the presence of well formed acini, evidence of anaplastic cell growth should be required. Clumped mesothelial cells frequently resemble neoplastic cells (Fig 5) and may show such features as mitotic figures and binucleate forms. Such cells, however, do not have

significant irregularity in arrangement and staining of nuclear chromatin, marked variation in size of

positive diagnosis. Regarding the value of single cells in arriving at a correct diagnosis, we are in

but by rigidly demanding definite evidence of anaplasia in such cases, one can usually arrive at

on the basis of single cells, regardless of atypical features.

The large number of specimens that were reported as showing insufficient sediment for examination was undoubtedly due to the fact that suitable technics were not invariably employed. In our limited experience, we have failed to obtain sufficient sediment in only 1 case, although we have seen many specimens in which settling overnight failed to produce a cloudy layer on the bottom of the container. The application of Schlesinger's method of successively centrifuging 50-cc lots of the specimen in the same centrifuge tube or the use of a modifica-

Bronchiogenic carcinoma extends or metastasizes to the pleura, according to Honigman, in less than a third of all cases. Our finding that 25 per cent of the specimens of pleural fluids submitted on patients suffering from this type of malignant neoplasm yielded positive cell blocks thus appears not unreasonable.

The most frequent non-neoplastic causes of serous effusion in our series were heart disease (12 cases), cirrhosis of the liver (12 cases) and pulmonary or peritoneal tuberculosis (10 cases). Since tuber-

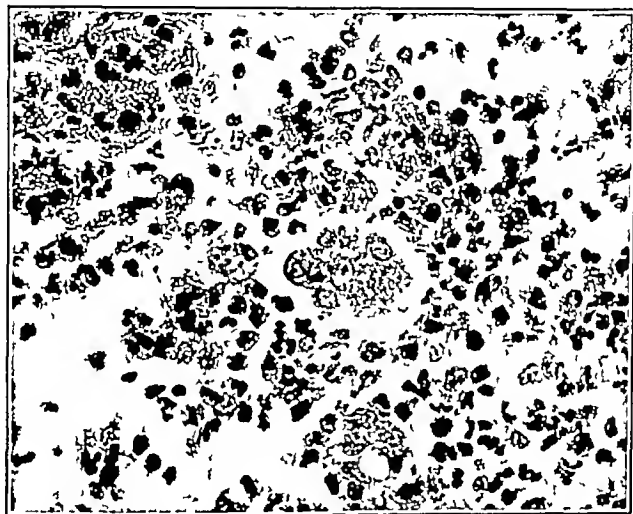

FIGURE 5 Clumped Mesothelial Cells from Ascitic Fluid in a Case of Alcoholic Cirrhosis (x560)
The cells appear to form a crude acinus but no definite evidence of anaplasia can be made out

tion of the Alzheimer technic invariably provides sufficient sediment for examination.

Table 2 shows that positive cell blocks were most frequently seen in cases of carcinoma of the ovary, the next most frequent, in order, being carcinoma of the breast, pancreas, stomach, kidney and lung. In Schlesinger's study 100 per cent of cases of carcinoma of the ovary yielded positive cell blocks, the next most frequent types being carcinoma of the stomach, lung, colon and breast in that order. The orders in Honigman's and Zemansky's series vary somewhat from that in our own, but it is noteworthy that carcinoma of the ovary, breast, lung and gastrointestinal tract ranks well up in all the series. That carcinoma of the ovary should figure so prominently in all four studies is hardly surprising, since the tendency of the growth to produce serosal carcinomatosis and effusion is well known.

culous fluids often contain viable tubercle bacilli and are potentially infectious, proper precautions should be observed in the preparation of cell blocks from any serous effusion.

As noted in Table 1, falsely positive diagnoses were made on cell blocks from 3 cases showing no evidence of malignant neoplasm at autopsy. In 1 of these the fluid, thought to be ascitic fluid, actually was withdrawn from a large pancreatic cyst and contained well formed acini (Fig 6). These were presumably from the pancreas itself and were composed of cells showing no conclusive evidence of anaplasia. In the other cases the accumulation of ascitic fluid was apparently due to hepatic cirrhosis of long standing, and the cells thought to be neoplastic cells were actually atypical or clumped mesothelial cells (Fig 5).

THE OCCURRENCE OF CARCINOMA OF THE THYROID GLAND IN AUTOPSY MATERIAL*

W P VANDERLAAN, M D †

BOSTON

THERE is ample reason for confusion in attempting to interpret recent clinical and pathological reports concerning both benign and malignant neoplasms of the thyroid gland in their relation to nodular goiter. Several papers have stressed the high incidence of cancer in nodular goiter. Thus, Ward¹ found an incidence of 4.8 per cent, and Cole, Slaughter and Rossiter² one of 7.2 per cent. Furthermore, Hinton and Lord³ observed a higher incidence of cancer in apparently benign nodular goiters (7.6 per cent) than in innocent appearing "lumps" in the breast (6.7 per cent) and therefore concluded that it is as justifiable to do a thyroidectomy for nodular goiter as a biopsy for a mass in the breast.

In view of these observations considerable interest attaches to other data indicating that nodules in thyroid glands are found at autopsy with some frequency. In a goitrous area — Chicago — Jaffé⁴ found nodules in the thyroid glands at autopsy in 30.0 per cent of white men, 44.7 per cent of white women, 14.5 per cent of Negroes and 25.5 per cent of Negroes. Despite this high incidence of nodules, only 2 cases of carcinoma were observed in 1000 cases. On the other hand, in a nongoitrous area — Boston — Schlesinger, Gargill and Saxe⁵ reported that 8.2 per cent of all thyroid glands examined at autopsy contained distinct nodules more than 1 cm in diameter, and in nodular goiters from 112 cases they found 5 carcinomas (4.5 per cent) and 1 sarcoma. This higher incidence of carcinoma in nodules in the nongoitrous area may be related to the observations of Warren⁶ that true adenomas are rarely multiple and are to be distinguished from the nodules of endemic goiter and that isolated nodules are ten times likelier to be malignant than any other type of thyroid enlargement. Thus, it might be considered that in a nongoitrous area adenomas comprise a higher proportion of thyroid nodules and hence that the percentage of carcinomas in such nodular goiters is greater than that in a goitrous area, where nodules are more frequently those of endemic goiter.

Again, however, a difficulty similar to that observed by Cole et al.,² who found 11 per cent of 100 cases of multinodular nontoxic goiter to be malignant, arises. According to Warren's view it is unlikely that these multinodular goiters were true adenomas, they appear to have been multinodular

endemic goiters. It is perhaps noteworthy that the surgical material of Cole et al. is drawn from the Chicago area, as is Jaffé's autopsy material. The application of Cole's finding that 7.2 per cent of all nodular goiters are malignant to Jaffé's figure that at autopsy nearly 30 per cent of all thyroid glands contain significant nodules means that thyroid carcinoma should be present in about 2 of every 100 cases at autopsy. Actually, Jaffé found a ratio of 2:1000.

From such considerations it seems apparent that the relation of neither neoplasia nor cancer to nodular goiter is yet clear. They serve rather to emphasize that the morphologic diagnosis of carcinoma of the thyroid gland is frequently difficult and that criteria that suffice for one pathologist are deemed insufficient by another. It seems clear, however, that the ultimate criterion for the diagnosis of cancer is that the disease naturally results in the death of the patient harboring it. It thus appeared to be of interest to review the autopsy material of the Boston City Hospital to establish the frequency with which carcinoma of the thyroid gland was found as a cause of death, for such data provide a good indication of the incidence of this disease in an unselected population. It is, of course, appreciated that any figure obtained will probably be somewhat lower than the incidence for the population as a whole, since patients of this type are rarely permitted to remain on the wards of a large general hospital, being sent home or elsewhere for the terminal stages of their disease.

The material reviewed comprised the 18,668 cases seen at autopsy in the half century from 1896 through 1945. In this period 5 cases of carcinoma of the thyroid gland occurred, in 1 it was an incidental finding at autopsy, and in 4 it was widespread and had resulted in death.

This number may be compared with those of other relatively infrequent diseases. Thus, carcinoma of the adrenal gland was more than three times more frequent, occurring in 17 cases during the same period. The incidence of primary carcinoma of the liver was much greater — 34 cases. Similarly, 30 cases of benign pituitary tumor occurred in the same period, and, in addition, there were 2 cases of carcinoma of the pituitary body. Perhaps the most striking indication of the rarity of carcinoma of the thyroid gland at autopsy is the observation that carcinoma of the duodenum, occurring in 11 cases, was twice as frequent as the former condition.

In addition to the autopsy material of the Boston City Hospital, the autopsy figures of the Peter Bent

*From the Mallory Institute of Pathology, Boston City Hospital.
†This work was performed under a fellowship of the American Cancer Society recommended by the Committee on Growth of the National Research Council.

†Formerly assistant resident in pathology, Boston City Hospital; fellow of the American Cancer Society. Joseph H. Pratt, Diagnostic Hospital.

Brigham Hospital and the Massachusetts General Hospital, through the courtesy of Drs T D Kinney and Tracy B Mallory, respectively, were made available. Cancer of the thyroid gland was found to have been the cause of death in 5 cases among more than 6000 examined at autopsy at the Brigham Hospital, and the incidence of cancer of the thyroid gland was less than 1/1000 in 11,000 autopsies at the Massachusetts General Hospital. As in the Boston City Hospital series, these figures indicate a low incidence of cancer of the thyroid gland. It is of interest that in Ophuls's⁷ series of 3000 autopsies, no thyroid cancer was found.

In view of the relative infrequency with which carcinoma of the thyroid gland has been found as a cause of death in a large autopsy experience, it seems reasonable to suggest that the pathological criteria for this diagnosis should be reviewed in cases in which microscopical examination of thyroid nodules has led to the conclusion that carcinoma of the thyroid gland is of frequent occurrence.

SUMMARY

In the half century from 1896 through 1945, a total of 18,668 autopsies were performed in the

Boston City Hospital, and carcinoma of the thyroid gland was found in 5 cases. Carcinoma of the adrenal gland was three times and primary carcinoma of the liver and pituitary-body tumors six times more frequent, even carcinoma of the duodenum exceeded this incidence by more than twice. At the Peter Bent Brigham Hospital and the Massachusetts General Hospital, cancer of the thyroid gland was the cause of death in less than 1/1000 cases at autopsy.

It is concluded that carcinoma of the thyroid gland is a rare cause of death.

CHICKEN POX WITH SIMULTANEOUS IDIOPATHIC THROMBOCYTOPENIC PURPURA*

Report of a Case

JEROME J COHEN, M D,† AND CHARLOTTE BANSMER, M D‡

WORCESTER, MASSACHUSETTS

CHICKEN pox is generally considered a benign disease. The following case was accompanied by primary idiopathic hemorrhagic purpura. Since similar reported cases are few and all indicate a grave prognosis, this case is presented.

An 11-year-old boy entered the hospital because of a hemorrhagic vesicular rash, petechiae, ecchymosis, epistaxis, melena and hematuria. He had been perfectly well until 3 days before admission, when a slight fever, nausea and vomiting and headache developed. On the following day a vesicular eruption appeared on the head, face, neck and upper chest. During the next 24 hours these vesicles became hemorrhagic, petechiae, purpuric spots and ecchymoses appeared on the skin between the vesicles. The hemorrhagic areas of the skin were widespread. Bleeding from the mucous membranes was also present. Because the patient had developed slight difficulty in breathing and the hemorrhage had continued he was admitted to the hospital.

The patient was the fifth child in a family of seven. Delivery had been normal at full term, the birth weight being 12½ pounds. He had been breast fed for the first 9 months. Solid foods were added at the age of 4 months. Cod-liver oil and orange juice were given from early infancy. The patient had never presented a feeding problem. He had first walked at 14 months of age, otherwise, development had been entirely normal. At 3 years of age he suffered a minor trauma to the head, subsequently strabismus of the

right eye was noted. He had had measles, mumps and whooping cough, all in mild form. He had never had chicken pox. He had been vaccinated at the age of 6 years. There had been no operations or injuries and no previous bleeding tendencies. Progress in school had always been slow, and at the time of admission the patient was in the third grade. The other children in the family progressed normally in school. The patient had never exhibited any behavior difficulty in school, at home or at play.

The mother, who was 47 years old, had diabetes mellitus, which was treated by diet alone. She had been aware of this condition for the previous 2 years. The father, aged 47 years, was well. Both maternal grandparents had died of diabetes. Four brothers were well. An 8-year-old brother had had typical, uncomplicated chicken pox 2 weeks previously. This brother had also been vaccinated at the age of 6. Six sisters were well. There was no family history of tuberculosis, blood dyscrasias, heart or kidney disease, venereal disease or cancer.

Physical examination revealed a well developed and well nourished boy, who was co-operative and well oriented. Bright blood was oozing from both the nose and the mouth. The pupils were round, regular and equal and reacted to light and accommodation. There was a right internal strabismus, as well as large subconjunctival hemorrhages bilaterally. The right otic canal was clear, and the drum normal. The left canal showed evidence of hemorrhage, the drum could not be visualized. The tonsils and pharynx contained purplish vesicles. The tonsils were not enlarged, and there was no exudate or inflammation. The mucous membranes of the mouth contained numerous hemorrhagic vesicles. The tongue was slightly swollen, with purpuric spots scattered over the surface. The neck, chest, lungs and heart were normal.

*From the Contagious Department, Belmont Hospital.

†Assistant pediatrician, Worcester City Hospital; assistant pediatrician, Belmont Hospital.

‡Resident physician, Belmont Hospital.

The abdomen was not tender and the liver and spleen were not palpable. The genitalia were normal. Examination of the rectum disclosed no masses and there was no blood on digital examination. The reflexes were normal.

There were numerous hemorrhagic vesicles, mostly on the scalp and the skin of the head, neck, upper extremities and chest (Fig. 1). There were a few such lesions on the palms of both hands and on the scrotum and penis. The vesicles were present in crops and were discrete and well demarcated.

thrombin time were normal. A blood Hinton test was negative. The albumin-globulin ratio was 1.5. All blood cultures were negative. On admission the bleeding time was 13½ hours and the clotting time 7 minutes and there was no clot retraction in 24 hours.

A diagnosis of hemorrhagic chicken pox was made on admission.

During the first 8 days in the hospital the patient had profuse epistaxis, melena and hematuria. The temperature

FIGURE 1 Photograph of the Patient Taken on the Day following Admission

Around each vesicle was a corona of subcutaneous hemorrhage that was confluent with that of the surrounding vesicles in some areas. Between the vesicles there were many petechiae and a moderate number of purpura and ecchymotic

was essentially normal, the highest recorded being 101°F by rectum on the 2nd hospital day. He was maintained by blood and plasma transfusions, receiving eight 500-cc. transfusions in all. In addition he was given parenteral fluids,

areas varying in size. A few similar lesions were present on the abdomen and the dorsal and lumbar areas as well as the lower extremities.

The pulse was 96 and the respirations 20. The blood pressure was 110/68.

The pertinent laboratory findings are presented in Table I. The blood sugar, nonprotein nitrogen, icteric index and pro-

teins and iron and ammonium citrate. Penicillin was administered intramuscularly as prophylaxis against secondary infection. The patient was in shock on two occasions during this period and responded to ordinary shock measures including oxygen therapy. A skin biopsy at the height of the disease showed chronic inflammation and hemorrhage of the dermis. On the 8th hospital day a sternal marrow puncture

performed by Dr William Dameshek was typical of idiopathic thrombocytopenic purpura

The bleeding gradually subsided, and the patient's general condition improved consistently. The skin lesions became crusted, and the crusts fell off with no residual scarring. The subcutaneous hemorrhages cleared. He was discharged on the 30th hospital day in good condition.

The patient was seen at intervals of 2 weeks for 2 months after discharge. The blood findings remained essentially normal. His general physical condition was good, with full activity. No enlargement of the spleen was noted.

In a review of the literature the incidence of hemorrhagic chicken pox was found to be extremely low.¹⁻¹² The majority of cases reported do not include significant hematologic data. The clinical courses in these cases, however, closely parallel that in the case reported above except that the greater proportion terminated fatally, there being 6 deaths in the 9 cases. None of these patients were given intensive blood-replacement therapy. The cases that include hematologic data substantiate the simultaneous occurrence of idiopathic thrombocytopenic purpura.^{1, 2, 11, 12} All the patients recovered, although in 1 case there was extensive gangrene, necessitating amputation.¹¹ In no case was there a history of a bleeding tendency or blood dyscrasia.

The case presented above, because of its symptomatology and blood findings, was deemed worthy of report in view of the severity of the symptoms. Transfusions were indicated to replace blood loss. The use of moccasin venom was considered but rejected. This venom was used in the early phase of the disease in the case reported by Stoesser and Lockwood.¹¹ Subsequent exacerbations of purpura in the same case, however, were treated by transfusions alone. The blood findings in the case presented above indicated idiopathic thrombocytopenic purpura, and this was substantiated by sternal puncture. It was believed that if the platelet count did not rise a splenectomy should be con-

sidered. The use of anticytotoxic serum was suggested by Dr Dameshek, but because of the spontaneous improvement in the platelets and general blood picture, this was not used.

SUMMARY

A case of chicken pox with simultaneous idiopathic thrombocytopenic purpura is presented. Recovery was complete, and follow-up study showed that the patient had a normal blood picture and was in good health eight months after the acute illness.

Treatment was directed toward combating the effects of blood loss. Specific treatment of the purpura with anticytotoxic serum was considered but, because of the rapid improvement in the blood picture, was not used.

A review of the literature indicated the rarity of hemorrhagic chicken pox and its grave prognosis and suggested that all cases when investigated thoroughly from a hematologic point of view entail two entities: chicken pox and idiopathic thrombocytopenic purpura.

MEDICAL PROGRESS

CURRENT CONCEPTS OF JAUNDICE, WITH PARTICULAR REFERENCE TO HEPATITIS*

LAWRENCE E. YOUNG, M.D.†

ROCHESTER, NEW YORK

JAUNDICE—or yellow staining of the skin, mucous membranes and scleras due to the presence of excessive amounts of bilirubin in the blood—can probably be produced by as great a variety of pathologic processes as any physical finding encountered in the practice of medicine.¹⁻⁴ Since bilirubin is derived from hemoglobin, an understanding of the numerous mechanisms by which jaundice may develop is best approached by a review of certain aspects of the normal metabolism of hemoglobin.

NORMAL BILE-PIGMENT METABOLISM

As shown in Figure 1, the porphyrin rings of the hemoglobin molecule are made up of four pyrrol nuclei each, the iron-porphyrin complexes being best designated as "heme." There are four heme molecules attached to each molecule of globin, but, to conserve space, only one has been shown in the illustration. Although the exact manner in which red cells are destroyed in the reticuloendothelial system is not understood, it is likely that the porphyrin ring of the liberated hemoglobin is broken at the alpha-methene bridge, iron is removed,⁵ and the resulting iron-free compound is probably bilirubinogen, whose structural formula is demonstrated in Figure 2. According to Watson⁶ globin, a protein of about the same molecular weight as albumin, is attached to the pyrrol nuclei by carboxyl groups, as in the hemoglobin molecule. Bilirubinogen is transported in the blood to the liver, where bilirubin is separated from globin and excreted in the bile as sodium bilirubinate.

When bile reaches the colon, bilirubin is reduced by the bacterial flora to urobilinogen, which is a colorless compound having a structural formula like that of bilirubin except for the presence of additional hydrogen atoms. Actually, two urobilinogens (mesobilirubinogen and stercobilinogen) are formed in the bowel, but they are best referred to collectively simply as urobilinogen, since the chemical tests for

their measurement quantitate them as though they were a single compound.⁷ Urobilinogen is readily oxidized to urobilin, an orange-yellow pigment, which is partly responsible for the color of normal stools. Inasmuch as the quantitative chemical determinations of urobilinogen involve reduction back to urobilinogen of any urobilin present, it seems reasonable to omit from most of this discussion the term urobilin as well as the confusing terms, stercobilin, stercobilinogen and mesobilirubinogen. It is adequate for the purposes of this paper to discuss hemoglobin breakdown in terms of bilirubin and urobilinogen only.

The amounts of the natural derivatives of hemoglobin that are metabolized daily in a normal person can be readily calculated. If the total blood volume is 5000 cc and the hemoglobin concentration is 15 gm per 100 cc, the quantity of circulating hemoglobin is 750 gm. The average life span of erythrocytes in normal human beings is about one hundred and twenty days, which means that 0.83 per cent of the hemoglobin mass, or 6.22 gm, is destroyed and replaced daily.⁸⁻⁹ In normal persons destruction is thought to be confined largely to the oldest cells—that is, those about one hundred and twenty days old. Since the breakdown of 1 gm of hemoglobin results in the formation of approximately 35 mg of bilirubin,¹⁰ which is excreted quantitatively,¹¹ approximately 220 mg of bilirubin is formed daily in the reticuloendothelial system and excreted into the bile by the liver. Since the molecular weight of urobilinogen is nearly the same as that of bilirubin, if all the bilirubin excreted each day is reduced in the colon to urobilinogen, approximately 220 mg of urobilinogen is formed daily.

The steps that normally lead from the destruction of red corpuscles to the excretion of urobilinogen are reviewed in Figure 3. So far as is known, the chemical changes involved take place in three sites—the reticuloendothelial system, the liver and the colon. In normal mammals most of the bile pigment is probably produced in the reticuloendothelial cells of the bone marrow, whereas the spleen and the

*Presented in part at the annual meeting of the Vermont State Medical Society, Burlington, Vermont, October 4, 1946 and at a joint meeting of the Council of Rochester Regional Hospitals and the staff of the Veterans Administration Hospital, Bath, New York, November 14, 1946.

1. A complete review of the many controversial aspects of normal and abnormal bile-pigment metabolism. The aim has been merely to present, with illustrations, concepts that seem currently to be most acceptable and most contributory to an understanding of the pathogenesis of jaundice.

†Henry C. Bassell Fellow in Medicine, University of Rochester School of Medicine and Dentistry.

11. It is likely that, when the alpha-methene bridge of the porphyrin ring is removed the compound formed is verdohemoglobin, a biliverdin iron globin, which is subsequently converted to bilirubinogen.

Hawkins and Johnson¹⁰ explain that it has been customary to use the equation 40 mg of bilirubin = 1 gm of destroyed hemoglobin, since the pigment radical comprises 4 per cent of the hemoglobin molecule. These authors point out, however, that bilirubin has a molecular weight of 584 and heme a molecular weight of 632, and that 1 gm of hemoglobin contains 3.35 mg of iron. On the basis of these data it is calculated that 34.9 mg of bilirubin should be derived from the destruction of 1 gm of hemoglobin. It is well to add that the quantitative conversion of heme to bilirubin especially under pathologic conditions, is questioned by some authors,¹² and that much remains to be learned concerning the breakdown of hemoglobin and myoglobin to dipyrromethenes.¹³

Kupffer cells of the liver have a relatively minor role. Contrary to older views, the polygonal cells of the liver have only an excretory function so far

unknown. It is unlikely, however, that the pyrrole nuclei of the absorbed urobilinogen molecules are reutilized in hemoglobin formation, since pyrrole aggregates can probably be readily synthesized.¹¹ A small fraction of the absorbed urobilinogen passes through the liver to the hepatic veins, enters the

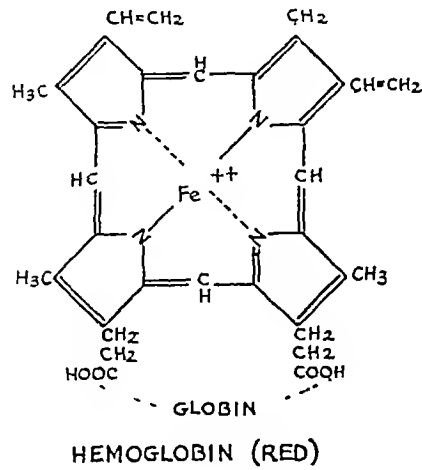

FIGURE 1 Structural Formula of Hemoglobin

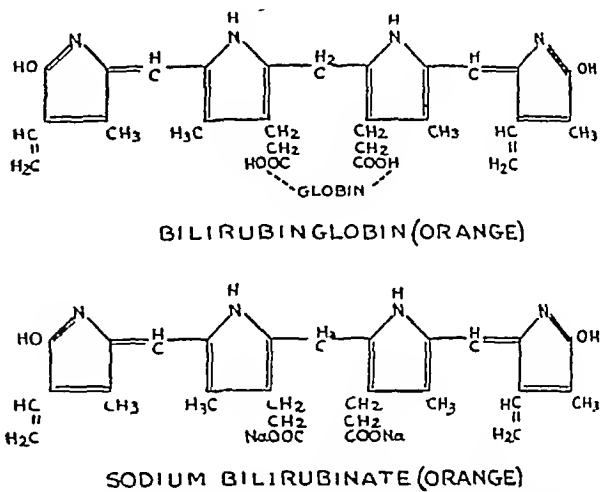

FIGURE 2 Structural Formulas of Bilirubin and Sodium Bilirubinate

as bile pigment is concerned, and are not involved in the initial steps of hemoglobin breakdown.^{13, 14} The greater part of the urobilinogen formed in

general circulation at the vena cava and is eventually excreted into the urine by the kidney. The normal range for urinary urobilinogen in adults is from

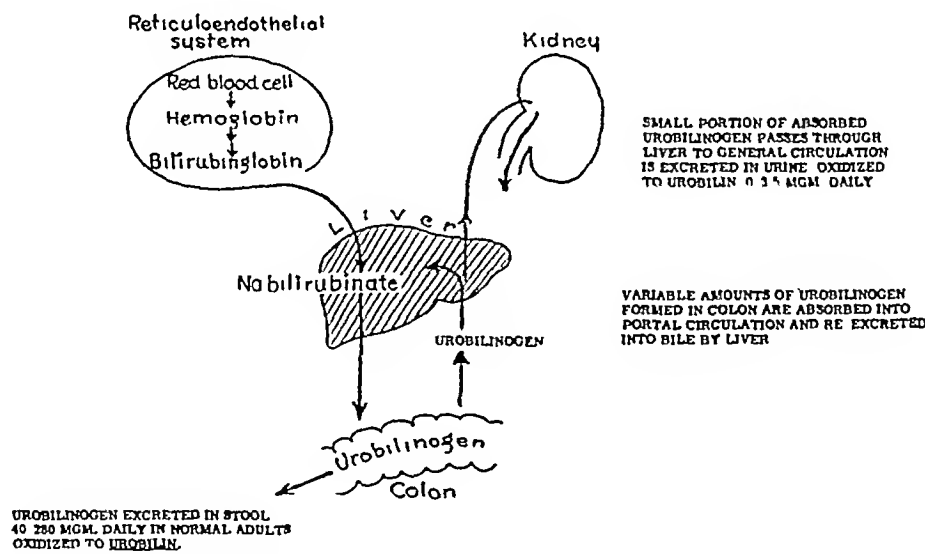

FIGURE 3 Diagram of Steps Leading from Destruction of Red Corpuscles to Excretion of Urobilinogen in Normal Subjects

the colon is ordinarily excreted in the stool, in which it is oxidized to urobilin, but a portion is reabsorbed into the portal circulation, transported back to the liver and re-excreted in the bile. The exact manner in which urobilinogen is handled by the liver is

0 to 3.5 mg a day, whereas the normal range for fecal urobilinogen is from 40 to 280 mg a day.¹⁵
ABNORMAL BILE-PIGMENT METABOLISM
With the basic facts concerning normal pigment metabolism in mind, the abnormalities of these

processes that are observed in the various pathologic states accompanied by jaundice may be considered Rich¹ has placed all the forms of jaundice in two large groups. The first type is called "retention jaundice" because bilirubin is retained in the blood

obstructive, mechanical and surgical types referred to by various authors. Although no single classification is entirely adequate, the merits of Rich's concept become apparent when the mechanisms responsible for jaundice and the clinical laboratory

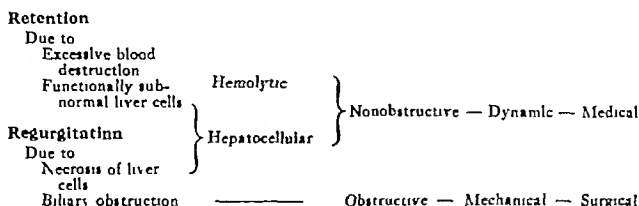

FIGURE 4 Interrelations of Various Classifications of Jaundice

owing to the inability of slightly subnormal liver cells to excrete the amounts of this pigment that are presented by the blood for clearance. The

tests used in differential diagnosis of the various forms are considered.

Figure 5, which is a modification of a drawing by Rich,¹ presents diagrammatically the histology of the normal liver lobule. The sinusoids lie between the cords of liver cells and carry blood from branches of the portal vein and hepatic artery to the central vein of the lobule, from which blood flows to the hepatic vein and thence to the vena cava. As blood flows through the sinusoids, certain substances, such as bilirubinglobin, are taken up by the polygonal cells and the Kupffer cells, and other substances are released from these cells to the blood. The tiny bile capillaries or canaliculi that lie between the individual polygonal cells are not ordinarily seen in sections of normal liver but are shown diagrammatically in Figure 5. The canaliculi receive freed bilirubin or sodium bilirubinate and other elements

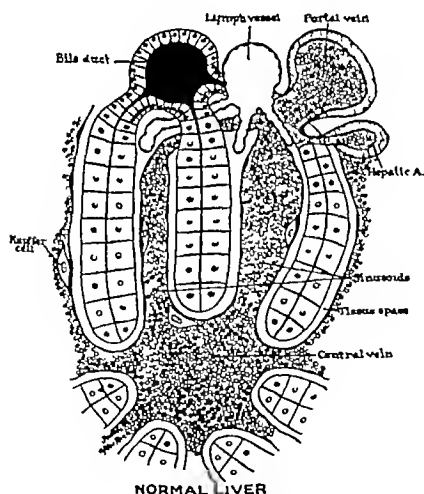

FIGURE 5 Diagram of Portion of Normal Liver Lobule (modified from Rich¹)

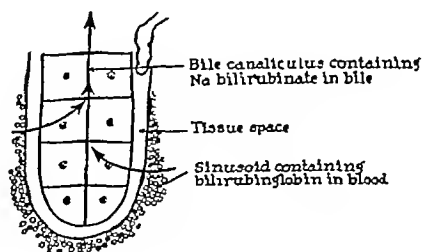

FIGURE 6 Diagram Indicating Direction of Normal Flow of Bile

second type is called "regurgitation jaundice" because it results from the escape or regurgitation of whole bile from the bile canaliculi into the blood stream. Retention jaundice includes the hemolytic, mild hepatocellular and nonobstructive types and dynamic or medical cases of other classifications (Fig. 4). Regurgitation jaundice, on the other hand, comprises the severe hepatocellular and the

of the bile from the polygonal cells and discharge them into branches of the hepatic duct located at the periphery of each lobule. The tissue spaces

between the sinusoids and the cords of liver cells are shown in exaggeration because of their importance in explaining the pathogenesis of jaundice. The supposed relation between tissue space and the lymphatic system is also apparent from this diagram.

In Figure 6, arrows indicate the direction of the normal flow of bile. Bilirubin enters the polygonal cells either directly from the sinusoidal blood or via the Kupffer cells, and sodium bili-

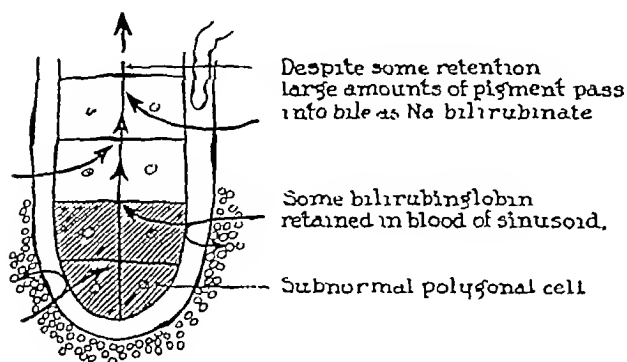

FIGURE 7 *Abnormality of Bile-Pigment Excretion in Retention Jaundice*

Bilirubin is retained in blood owing to overproduction (excessive destruction of red cells) or inability of subnormal liver cells to clear pigment, or both

rubinate is discharged into the bile canaliculi. It is not known whether protein (probably globin) is separated from bilirubin by the Kupffer cells or by the polygonal cells,⁶ but for the sake of simplicity, the illustrations and discussion that follow are based on the assumption that this separation is effected within the polygonal cells.

RETENTION JAUNDICE

Figure 7 illustrates the abnormality that is thought to be present in retention jaundice. The polygonal cells are anatomically intact, but some of them are functionally inadequate, with the result that a portion of the bilirubin is refused by the cells and retained in the blood. This is particularly true in hemolytic disorders in which the rate of hemoglobin turnover may be greatly accelerated and in which tremendous quantities of bilirubin are offered to the polygonal cells. The liver has an enormous reserve in its capacity to excrete bile pigment, and Rich¹ therefore believes that jaundice rarely develops from overproduction of pigment alone. The combination of pigment overproduction and functional impairment of polygonal cells, however, often produces jaundice.

In hemolytic anemia the liver cells may have reduced functional capacity due to anoxemia¹ and to the toxic effects of the products of excessive erythrocyte destruction.¹⁶⁻¹⁸ Since these cells are

unable to excrete the excessive quantities of bilirubin produced by the reticuloendothelial system, this pigment is retained in the blood and the result is clinical jaundice. Similar mechanisms may operate in pernicious anemia. In congestive heart failure the polygonal cells likewise suffer from anoxemia (stagnation and anoxic), and it seems likely that the so-called "heart-failure cells" of the lung and reticuloendothelial cells in other parts of the body break down a sufficient excess of hemoglobin from stagnated erythrocytes to burden the subnormal liver with more bilirubin than can be accepted. This process is more pronounced after pulmonary infarction not only because of increased blood destruction in the lung but also because anoxemia is intensified and some substance that further impairs liver function may be elaborated in the infarct.¹⁶ Retention jaundice likewise occurs in pneumonia due to anoxemia (anoxic) and to toxic insults to the liver cells in association with increased blood destruction by macrophages within the lung. Icterus neonatorum is another example of retention jaundice. The newborn infant responds to the polycythemic state by destroying large numbers of red cells during the first few days of life, and according to Rich,¹ the liver of the newly born is immature and apparently incapable of accepting the amounts of pigment produced. That the pathogenesis of icterus neonatorum is not entirely clear, however, is emphasized by the observations of Lin and Eastman,¹⁹ who found that newborn infants excrete intravenously injected bilirubin at a normal rate.

It is now recognized that a substantial number of otherwise normal persons have an icteric index and serum bilirubin concentration that are well above the normal range, and on close inspection these people are often found to have slight icterus of the skin and scleras. If bilirubin is injected intravenously it is excreted at a relatively slow rate.²⁰⁻²² Although insufficient pathological studies have been made in such cases, it now seems likely that many of these subjects can be placed in one of two groups. Those with little or no evidence of hepatic or hematologic abnormality other than impaired bilirubin excretion may have what is called "constitutional hepatic dysfunction," a benign disorder that is also referred to as "familial nonhemolytic jaundice" when a familial distribution can be demonstrated.²¹⁻²⁷ It has been suggested that those with other evidence of liver disorder in addition to impaired bilirubin excretion may be suffering from the residual effects of toxic or infectious hepatitis.^{20, 22} The natural history of the infectious variety has been clarified in recent years, and it is now appreciated that in some cases evidence of hepatitis persists for long periods after the initial attack.²⁸⁻³⁴

In constitutional hepatic dysfunction the sole defect is thought to be an inborn inferiority of otherwise normal liver cells regarding excretion of

bilirubinogen This pigment is therefore retained in the blood in excessive amounts, even though the rate of erythrocyte destruction is normal. This is in contrast to the other examples of retention jaundice in which overproduction of pigment and diminished excretory ability of the liver combine to produce the icteric state. Further study will be necessary to determine the extent to which some cases of mild hepatitis and some cases of late con-

chronic hepatitis and cirrhosis has, however, been appreciated only in recent years.²²⁻²³ An understanding of the etiology and pathogenesis of infectious hepatitis and serum hepatitis has been reached even more recently. Investigations of hepatitis were, in fact, among the major contributions of military medicine during World War II and are therefore given separate consideration below.

Due to Biliary Obstruction

Because of the liver's enormous reserve, jaundice does not ordinarily result from biliary obstruction unless the flow of bile through the major part of the duct system is prevented.¹ When this occurs, the ducts and canaliculi are overfilled with bile (Fig 9), the tips of the canaliculi bulge into the tissue space, and bile diffuses into this space and thence to the lymphatic vessels and to the general circulation via the thoracic duct.¹⁰⁻¹¹ The ampullae that connect the bile capillaries with the smallest bile ducts or canals at the periphery of the lobule

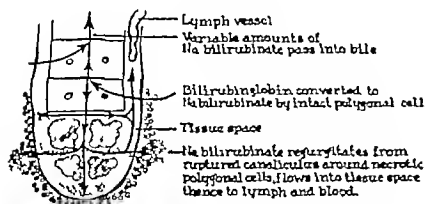

FIGURE 8 Mechanism of Regurgitation of Sodium Bilirubinate (and Other Bile Constituents) in the Presence of Hepatocellular Necrosis (after Rich)¹

valescent and chronic hepatitis may be considered instances of retention jaundice. It is pointed out below that typical bouts of acute hepatitis are examples of regurgitation jaundice.

REGURGITATION JAUNDICE

Due to Necrosis of Liver Cells

As stated above, regurgitation jaundice is due to a reflux of whole bile from the canaliculi into the blood stream. Figure 8, which illustrates the concept of Rich,¹ indicates that when some of the liver cells are necrotic, the adjacent bile canaliculi are no longer intact. Bilirubinogen passes through the remaining liver cells and is converted to sodium bilirubinate in the usual way, but a large portion of the freed bilirubin regurgitates around the necrotic cells and into the tissue space, entering the blood via the lymphatic system and perhaps also by diffusion into the sinusoids. Such a mechanism operates in many cases of hepatocellular necrosis regardless of etiology.*

Many of the causes of extensive liver-cell damage have been known to the medical profession for some time. Among these are chemical agents, such as chloroform, carbon tetrachloride, cinchophen and arsphenamine, infectious agents, such as the virus of yellow fever and the spirochetes of syphilis and Weil's disease, and metabolic disturbances, such as those that are thought to occur in eclampsia. The role of dietary deficiency in the pathogenesis of

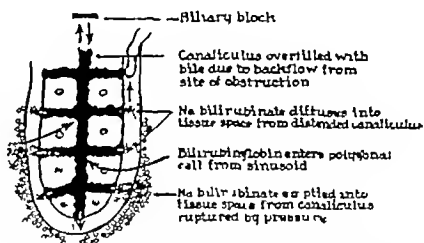

FIGURE 9 Mechanism of Regurgitation of Sodium Bilirubinate (and Other Bile Constituents) in the Presence of Biliary Obstruction (after Rich)¹

may act as safety valves by rupturing and thus reducing back pressure on the liver cells.²⁴ When pressure in the bile capillaries rises sufficiently, however, the capillaries rupture, and whole bile regurgitates freely into the tissue space, entering the blood stream via the lymphatic vessels and perhaps by diffusion directly into the sinusoids.

Most of the causes of extrahepatic biliary obstruction, such as tumor, stone and stricture, are well known and require no comment. The exact nature of so-called "intrahepatic obstructive jaundice,"²⁵⁻²⁶ on the other hand, is not well understood. Laboratory evidence of partial—and sometimes complete—biliary obstruction has been found in cases of hepatitis due to a variety of causes and with variable amounts of associated hepatocellular damage. Steigmann and Popper²⁴ emphasize the fact that in these cases the bile capillaries are dilated, whereas the larger ramifications of the biliary system beyond the ampullae are actually

* Watson²⁷ considers it possible that in regurgitation jaundice globin is removed by the Kupfer cells, after which bilirubin is reabsorbed by the polygonal cells and returns to the blood via the lymphatic vessels or possibly by direct diffusion into the sinusoids.

narrow. It is therefore held that obstruction must be present in the vulnerable ampullae that join the tiny bile capillaries with the smallest—variously named—bile ducts. It is thought that exudate may compress the ampullae, and that in some cases fibrous tissue may replace the exudate, causing the fixed obstruction of chronic hepatitis or cirrhosis. Bile plugs or thrombi, swelling of the liver-cell cords and edema formation in the tissue spaces surrounding the cords and the ampullae have also been suggested as causes of intrahepatic obstructive jaundice.

There is considerable difficulty in assessing the histologic findings in these cases, but further studies

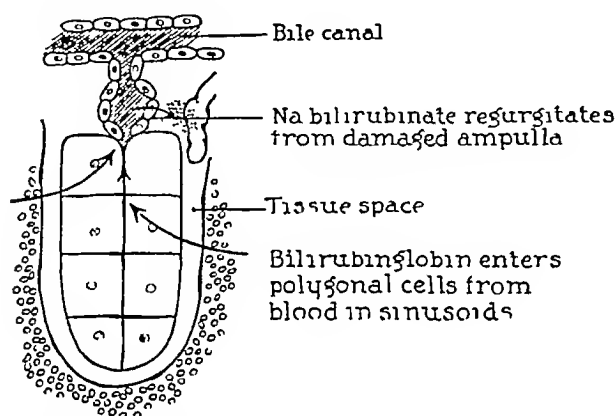

FIGURE 10 Mechanism of Regurgitation of Sodium Bilirubinate in the Presence of Cholangiolitis (modified from Watson⁵)

of autopsy material and of trocar aspiration biopsies of the liver obtained during different phases of hepatitis should serve to clarify the mechanisms of intrahepatic obstruction. In a personal communication Drs. Chester M. Jones and Wade Volwiler stated that, on the basis of recent, extensive observations, aspiration biopsy makes it possible to differentiate clearly jaundice due to hepatitis and that due to an otherwise silent or undiagnosed extrahepatic block. These investigators also emphasize the fact that properly prepared aspiration biopsies, when used in conjunction with laboratory tests, often enable the clinician to evaluate the phase of hepatitis with which he is dealing.

Due to Cholangiolitis

Watson and Hoffbauer³⁴ are of the opinion that in some cases of hepatitis, particularly those of the chronic type, regurgitation jaundice may be due chiefly to increased permeability of the cholangioles. According to their concept, which is illustrated in Figure 10, sodium bilirubinate escapes into the tissue space from the injured ampullae of the bile capillaries and presumably re-enters the blood via the lymphatic vessels or by diffusion into the

sinusoids. Since relatively more water and less solid matter would be expected to leak from the damaged ampullae, it is assumed that the bile remaining in the intralobular canaliculi tends to become inspissated, thus promoting the formation of bile thrombi. In some of the cases studied by Watson and Hoffbauer, however, bile thrombi were not conspicuous. Impressive evidence of other reputed causes of intrahepatic biliary obstruction, such as periportal cellular infiltration and swelling of liver-cell cords, was also lacking in their cases.

Regurgitation jaundice, regardless of its cause, is characterized by the escape into the circulation of bile salts and other constituents of the bile in addition to bilirubin. Accumulation of bile salts in the blood is considered a possible cause of pruritus—a symptom that is prominent in many cases of regurgitation jaundice, particularly those due to extrahepatic biliary obstruction, but is almost uniformly absent in retention jaundice. It should also be emphasized that in regurgitation jaundice, the bilirubin that re-enters the blood has been separated from globin by passage through the liver cells. Regurgitated bilirubin, perhaps because it is in the form of sodium bilirubinate, does not recombine with globin in the circulation⁵; it therefore readily passes the renal filter and also gives a direct van den Bergh reaction, as explained below.

(To be concluded)

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., Editor

BENJAMIN CASTLEMAN, M.D., Associate Editor

EDITH E. PARRIS, Assistant Editor

CASE 33331

PRESENTATION OF CASE

A fifty-five-year-old housewife entered the hospital because of jaundice.

Seven years before entry the patient had had an attack of jaundice and pain in the right upper quadrant. She was hospitalized for two weeks, during which time a Graham test showed no gall-bladder shadow. The symptoms disappeared, and bladder surgery was refused by the patient. For the past four years, and especially for the past seven months, the patient had lacked energy, had become easily fatigued and had considerable malaise. During the three weeks before entry she had been jaundiced and had noted dark urine, but she was vague about the color of the stools. No pruritus had been present. Small red spots had been noted on the arms. The appetite had completely disappeared. There had been no chills, fever, pain, nausea, vomiting or definite melena, although the stools were oc-

asionally dark. The diet was fat-free and low in protein. The patient said that she drank eight or nine small glasses of sherry and a little whisky each week.

Examination showed a markedly jaundiced, alert woman in no acute discomfort. There were numerous spider telangiectases over the thorax and arms. The abdomen was tense, with dullness in the flanks. The liver edge was palpable 6 cm. below the costal margin.

The temperature was 100.8°F., the pulse 85, and the respirations 18. The blood pressure was 125 systolic, 80 diastolic.

Examination of the blood showed a red-cell count of 3,600,000, with 12 gm. of hemoglobin, and a white-cell count of 18,500, with 82 per cent neutrophils. The urine gave a ++ test for albumin and a +++ test for bile, there was no sugar, and an essentially normal sediment. The stools were brown and guaiac negative. The stool urobilinogen was half that of a control. The prothrombin time was 18 seconds (normal, 15 seconds). A van den Bergh reaction was 18.4 mg. direct and 23.7 mg. indirect. The nonprotein nitrogen was 23 mg. per 100 cc., and the amylase, 24 units per 100 cc. The phosphorus was 2.4 mg., the alkaline phosphatase 16.2 units, the cholesterol 187 mg. and the cholesterol esters 99 mg. per 100 cc., the total protein was 5.9 gm. per 100 cc., the albumin being 2.9 gm. and the globulin 3.0 gm., an albumin-globulin ratio of 0.97. A blood Hinton reaction was negative. A cephalin-flocculation test was + in twenty-four hours and ++ in forty-eight hours.

A barium enema and chest films showed no abnormalities. A gastrointestinal series

large diverticulum arising from the second portion of the duodenum that could have been a barium-filled gall bladder. There was a fistulous tract from the second portion of the duodenum to the biliary tree (Fig 1). Whether this was regurgitation through the ampulla or through a biliary fistula was not ascertained.

The patient's hospital course was unsatisfactory. A high protein and vitamin intake was maintained by mouth and by use of a stomach tube and intra-

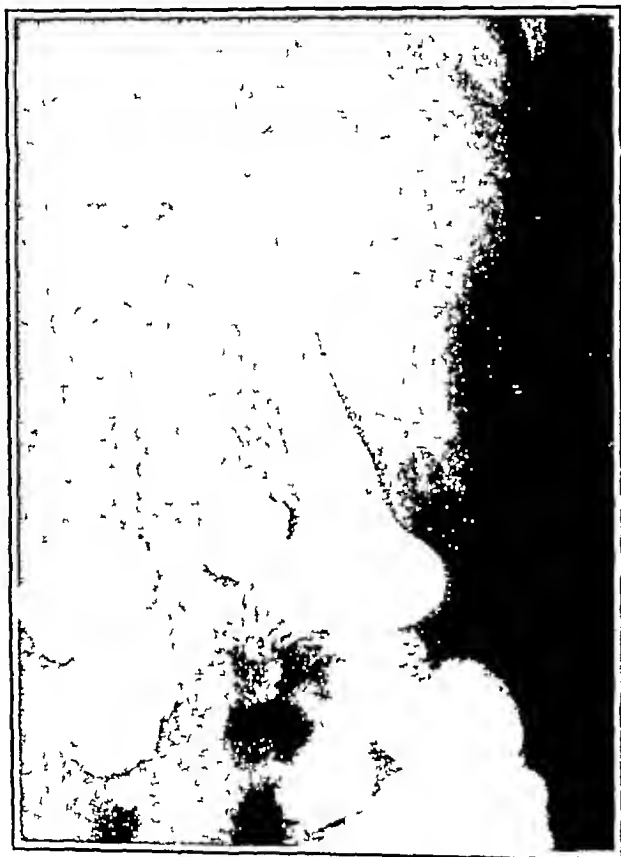

FIGURE 1 Barium-Filled Stomach and Duodenum. Barium is seen to ascend into the biliary tree — probably the common duct.

venous injections. The appetite remained poor. On the seventh hospital day the urine sediment contained numerous white cells, and the albumin rose to + + + +, no casts were seen, and a culture revealed colon bacilli. Three days later the white-cell count was 35,400. Streptomycin and penicillin were administered. The amount of albumin and the number of white cells in the urine diminished. Injections of Intrahepatol were given daily from the seventh to the thirteenth hospital day. Two transfusions were given without reaction. The patient became comatose on the twelfth hospital day, developed muscular twitching and incontinence of urine and feces and died on the eighteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR BERNARD M JACOBSON It is to be noted that although this patient had been ill for the past four years and especially during the past seven months, the jaundice was noted only about three weeks before entry. The statement is made that the abdomen was tense, with dullness in the flanks. We are not told about the presence of shifting dullness or fluid wave, and we therefore have no certain evidence of the presence of ascites. The liver edge was noted to be palpable 6 cm below the costal margin. I should certainly like to know where the upper border was percussed and what the edge was like. A liver edge felt 6 cm below the costal margin in a person whose upper border is percussed in the seventh space is compatible with a ptotic liver rather than a large liver. The blood findings were essentially those of a normocytic and normochromic anemia. The fact that the stools were brown rules out complete obstruction of the common bile duct. The presence of a biphasic van den Bergh reaction suggests diffuse liver-cell damage. The serum amylase of 24 units is not high enough to indicate pancreatitis. The high alkaline phosphatase was undoubtedly due to the jaundice. The cephalin-flocculation test also indicates diffuse hepatic derangement. A serum cholesterol level of 187 mg and a cholesterol ester level of 99 mg constitute a fairly normal ratio, if the cholesterol esters were markedly lowered in relation to the total cholesterol, the presence of severe liver-cell dysfunction would be indicated. The serum albumin was obviously low. This change could have been due either to diffuse hepatic disease or to poor protein intake, as suggested in the history. The results of the gastrointestinal x-ray studies leave me undecided about the presence of a cholecystoduodenal fistula. It is unfortunate that this point remains in doubt, for the presence of such a fistula would furnish strong evidence for a gall-bladder calculus. We are later told that the patient developed a urinary-tract infection, which undoubtedly was a terminal cystitis and possibly a pyelonephritis. I do not know what Intrahepatol is, but I presume that it is some form of crude liver extract. During the last six days of the patient's hospital stay, she was obviously suffering from acute liver failure. We have no clinical or chemical evidence that this terminal state was due to renal failure. In summary then, this patient undoubtedly died in terminal acute hepatic failure after a long siege of derangement of function of the liver or of the biliary tract or of both organs.

In view of the history of seven years of undoubted cholelithiasis with common-duct obstruction and of the possible presence of a cholecystoduodenal fistula, I am seriously thinking of obstructive biliary cirrhosis as the likeliest diagnosis. In keeping with this possibility are the facts that there was present only a moderate degree of liver enlargement and that

the jaundice appeared to be out of proportion to the size of the liver, in comparison, for example, with what might obtain in portal cirrhosis. The next likeliest possibility to explain the entire picture is portal cirrhosis. Against this diagnosis, however, is the fact that several characteristic findings are lacking. Thus, there is no obvious history of an excessive intake of alcohol or of hematemesis, there were no dilated veins over the chest and abdomen, no esophageal varices were noted in the gastrointestinal x-ray films, and the spleen is not described as enlarged. It is true, however, that none of the foregoing observations eliminate the possibility of portal cirrhosis. The age of the patient and the only slight enlargement of the liver, to my mind, furnish no evidence for biliary cirrhosis. Carcinoma, however, of either the liver, the biliary tree or the head of the pancreas cannot be lightly dismissed. Cancer in these locations is missed all too often in preoperative diagnoses. There is nothing in this patient's course that helps rule out carcinoma of the biliary tree or secondary carcinomatosis of the liver, but for the latter we have no knowledge of a primary source. There is no mention of a palpably large gall bladder, the obstructive jaundice was obviously not complete, and there was no x-ray evidence of compression of the duodenum, since these three points are lacking, the diagnosis of carcinoma of the head of the pancreas is unlikely. Finally, against the diagnosis of carcinoma is the long duration of the illness, if we assume that the patient had been suffering from the present illness for about four years.

I believe that the diagnoses that best fit the entire picture are obstructive biliary cirrhosis, due to calculus disease, and terminal acute hepatitis.

Dr. MILFORD D. SCHULZ. The film of the visualized upper gastrointestinal tract shows an essentially normal stomach and duodenum. There must be a communication between the biliary system and the duodenum, for barium is seen to ascend into the duodenum, but whether by way of a patulous ampulla or by way of a cholecystoduodenal fistula is not evident. The irregular collection of barium seen above the duodenal loop is probably a diverticulum of the duodenum but could conceivably be a barium-filled gall bladder, although it is in a rather unusual position. No varices are evident.

Dr. WADE VOLWILER. Many of us who saw the patient were inclined to consider a dual etiology of the fatal liver disease. The jaundice and the right-upper-quadrant abdominal pain seven years previously, coupled with the probable choledochoduodenal fistula, strongly suggested previous common-duct stones. It seems reasonable that some degree of biliary cirrhosis could have resulted from a relatively silent long-standing partial common-duct obstruction of a degree insufficient to produce continuous jaundice. The liver was large and firm. The amount of liver damage clinically present, however, seemed greater than what could be accounted

for on the basis of this simple explanation. There was, indeed, a rather impressive story of dietary inadequacy, which suggested that fatty infiltration of the liver from malnutrition and a mild but steady intake of alcohol was also present.

I thought that liver failure from the combination of these two distinct types of liver disease was precipitated by an acute exacerbation of bacterial cholangitis, which would explain the marked leukocytosis.

The liver-function tests did not help in the diagnosis. The cephalin-flocculation test was within the limits of normal. In this hospital the cholesterol-cholesterol ester ratio has proved to be extremely unreliable in confirming the presence or absence of parenchymatous liver disease.

The patient was treated intensively with food, whole-blood transfusions and antibiotics and was too ill for any truly definitive diagnostic procedures, such as liver biopsy.

CLINICAL DIAGNOSIS

Biliary cirrhosis, with cholemia

Dr. JACOBSON'S DIAGNOSES

Obstructive biliary cirrhosis

Terminal acute hepatitis

ANATOMICAL DIAGNOSIS

Acute cirrhosis of liver, alcoholic type

Dilatation of ampulla of Vater, with regurgitation of duodenal contents into bile ducts and gall bladder

Bile nephrosis

PATHOLOGICAL DISCUSSION

Dr. TRACY B. MALLORY. I am a confirmed skeptic regarding histories of alcoholism. A man's history should probably be doubled, a woman's tripled or quadrupled, and a teetotaler's discredited entirely. This woman died of acute portal cirrhosis of the liver of the type we ordinarily call "alcoholic," although most of us believe that alcohol is only indirectly responsible and that protein deficiency is the immediate cause of the liver injury. The liver was large, smooth, fatty, deeply bile stained and of slightly increased consistence. Microscopical examination showed marked fat vacuolization, many necrobiotic liver cells and the characteristic biliary degeneration of the type that my father, Dr. Frank B. Mallory, described as pathognomonic for this type of cirrhotic process. Further evidence of the acutely progressive character of the lesion was the infiltration of the tissues, both lobular and interlobular, with polymorphonuclear leukocytes. There was moderate proliferation of fibrous tissue, which tended to invade the lobules. The intrahepatic bile ducts were quite normal and showed neither proliferation nor inflammatory changes.

There was no fistulous connection between the biliary tract and small bowel, but the mouth of the common bile duct at the papilla was widely patulous and intestinal content was found in the common duct and gall bladder. The duct was dilated, but the gall bladder was of normal size, without evidence of inflammatory reaction. There were no stones. The spleen was moderately enlarged, weighing 370 gm, and the veins in the lower third of the esophagus were prominent but not demonstrably varicose. We found no pyelonephritis or cystitis, but the kidneys were somewhat swollen and showed microscopically a moderately severe grade of bile nephrosis.

CASE 33332

PRESENTATION OF CASE

A sixty-five-year-old man entered the hospital because of a mass in the lower abdomen.

Five years before admission the patient first noted decrease in the caliber of the stools. About three years before admission he had an ache and constant feeling of tiredness in the lower back. These symptoms became progressively worse. Three years before admission the abdomen was explored at an outside hospital, and a mass was found in the left lower quadrant. Excessive bleeding limited the operation to a biopsy, which was reported as showing "hemangioma." A positive blood Hinton test was found at that time, and the patient was treated with arsenic and bismuth for a period of nine months. Following operation the left leg became swollen, weak and tender. The patient slowly recovered, although weakness and numbness continued to bother him and the leg occasionally became swollen. During the hospital stay he lost an estimated 35 pounds in weight, which he never regained. During the three years before admission to this hospital the patient became progressively weaker, the mass steadily larger, and the constipation increasingly severer and just prior to admission he began to experience urgency, with a nocturia of one or two times, and a weakening of the urinary stream, without dysuria, hematuria or other genitourinary symptoms. The stools were never bloody or dark in color, and there was never more than minimal abdominal pain associated with bowel movements or otherwise. A thin, colorless "jelly-like" material was occasionally passed by rectum.

Physical examination showed a well developed but rather poorly nourished man. There was a definite bismuth line along the lower incisors. The heart and lungs were not remarkable. On examination of the abdomen a rounded, symmetrical protuberance was easily visible in the suprapubic area. It was firm, smooth and slightly tender, the upper limits could be easily outlined just below the umbilicus, but the lateral margins converged inferiorly. A soft, ballotable mass, which disappeared after voiding, was felt anterior to the large solid mass.

The rectum was narrowed and displaced to the right side of the pelvis by a lobulated portion of the mass that seemed to be firmly attached in the iliac fossa. No prostatic tissue could be felt on either side. The left leg showed moderate pitting edema to the knee. There was difficulty in dorsiflexing the left foot above a right angle, which was attributed to a tense Achilles tendon and not to weakness of the muscles of dorsiflexion. There was slight weakness of the psoas and quadriceps muscles on the left, but no reflex changes and no changes in sensation.

The red-cell count, white-cell count and hemoglobin were normal. The urine showed an occasional red cell, 4 or 5 white cells and an occasional granular and hyaline cast per high-power field. A stool gave a positive guaiac test. Blood Hinton and echinococcus skin tests were not reported. The nonprotein nitrogen was 37 mg and the total protein 7.2 gm per 100 cc, the chloride was 108 milliequiv per liter. The prothrombin time was 25 seconds (normal, 19 to 20 seconds). An x-ray film of the chest was normal. An intravenous pyelogram was unremarkable except for lateral displacement by the mass of the lower third of each ureter. There was no dilatation of the ureters or pelves, although no dye was seen in the bladder after twenty minutes. No involvement of the bony pelvis could be demonstrated. A barium enema showed marked displacement of the rectum and sigmoid to the right side of the pelvis (Fig 1), the latter being also pushed upward and, in its upper part, giving the appearance of attachment to the mass, elsewhere it was movable. On a post-evacuation film the greatest amount of the barium remained in the colon.

On the tenth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR EDWARD HAMLIN, JR. It seems to me that the problem here should be narrowed down to deciding what sort of mass was in the pelvis. If so, there are many possibilities. I hope that the x-ray films will be helpful.

DR STANLEY M. WYMAN. I should not call the lungs normal. Although the films were taken with the patient lying on his back, the hilar vascular shadows are more prominent than usual. I believe that there is considerable collapse of one or both lower lobes, which possibly suggests congestion and some atelectasis. An additional fact that may help is that this film, taken elsewhere three years previously, shows the rectum displaced to the right, with the sigmoid running over the mass. Our film shows that the mass is considerably larger.

DR HAMLIN. Is there any calcification?

DR WYMAN. I see no calcification in the mass.

DR HAMLIN. They are fascinating pictures but not particularly helpful. It seems from the appearance of the x-ray films that the mass lies retroperitoneally, otherwise it would not displace the

ureters and rectosigmoid to such an extent. So I shall limit myself to a discussion of retroperitoneal masses.

Was this a malignant or a benign tumor? There is little evidence to suggest that it was malignant. It might have been a malignant tumor in the sense that it would be locally recurrent when excised, but in the ordinary sense of invasive or metastasizing potentialities, the evidence is nil. So let us narrow ourselves down to the consideration of benign retroperitoneal tumors. By the way, was the patient proctoscoped?

Dr TRACY B MALLORY There was a note that they tried but were unsuccessful.

Dr HAMLIN I can well see why they could not.

We already have a positive diagnosis of hemangioma, and whether that is in the nature of a red herring or whether we are supposed to think that it is a red herring, I do not know. It is difficult to eliminate it entirely. We have evidence for a vascular tumor because the surgeon who operated backed out. It is possible that in the original operation some damage was done to the left iliac vessels, following which the patient had edema and some weakness of the left leg, although that is difficult to interpret.

There was a positive blood Hinton test. I have never heard of gumma of such a nature, and since I have never heard of it, I shall not discuss it further.

Someone did an echinococcus skin test, the results of which are not recorded. That sounds like another red herring because the evidence is so slim and also because a primary retroperitoneal echinococcus lesion is rare. I shall dismiss it.

Dr JOSEPH C AUB Where did the patient come from?

Dr MALLORY New Hampshire.

Dr HAMLIN Not a typical geographic location for echinococcus disease.

It simply comes down to my reciting the list of relatively benign retroperitoneal tumors and picking out one and saying, "That is it," because I have so little information that will give me any help, except the one thing that I have mentioned, namely, that it was vascular. Generally speaking, benign tumors are not vascular. I doubt that this was hemangioma. It is extremely unusual for such a tumor to produce a space-occupying mass of this size. It was also said to have been lobulated. Most of these tumors are lobulated. It conceivably could have arisen from the sigmoid, but the evidence for that is meager indeed. If it did arise in the sigmoid, one would postulate a leiomyoma, a neurofibroma or something of that nature. Chordoma may be found in that area, but no bony abnormality is recorded, and it is inconceivable that such a lesion could exist without bony abnormality. Then there are the fibromas, the myxomas and the lipomas. A lipoma of that size should be radiotranslucent, so I shall eliminate lipoma.

This is a rather typical place for enchondroma. The tumor was fixed. I should have expected that an enchondroma of this size would have shown calcification. The vascularity of the lesion is not explained by enchondroma.

There are a great many rare tumors, the gangliogliomas and so forth, but I doubt that any such tumor was found.

I am backed up to the wall here because I have no more leads for one type of tumor than for another.

FIGURE 1

Because enchondromas do exist in the pelvis, are lobulated and firm, and often displace viscera, as do lesions of these other types, to be sure, I shall "stick my neck out" and call it an enchondroma.

Dr MALLORY Are there any suggestions?

Dr GORDON A DONALDSON Could it be a meningocele?

Dr MALLORY This is the region for a meningocele, but I think that the X-ray Department would have had something to show if that were the case.

Dr WYMAN There is no evidence of spina bifida.

CLINICAL DIAGNOSIS

Retroperitoneal neurofibroma

Dr HAMLIN'S DIAGNOSIS

Sacral enchondroma

ANATOMICAL DIAGNOSIS

Retroperitoneal neurofibrosarcoma

PATHOLOGICAL DISCUSSION

DR MALLORY Dr Hamlin was skeptical of the previous biopsy report of hemangioma, and I think justly so. This would be an odd location for a huge hemangioma. My guess is that at the first biopsy only the capsule of the tumor was removed, which probably contained large vessels that suggested hemangioma. It is possible, however, that they actually got into the tumor and made that diagnosis. It sometimes is difficult to differentiate a scirrhous type of angioma and a vascular type of fibroma.

The tumor that Dr Carroll B. Miller resected was a large one, measuring 20 by 10 cm., and was adherent to all the retroperitoneal structures. Histologically it was a fibrous tumor of moderate cellularity, and we called it a low-grade neurofibrosarcoma, just on the borderline of malignancy from the histologic point of view. It was necessary in removing it to jeopardize the blood supply of the sigmoid, so that a resection of that had to be done, but it did prove possible to enucleate the tumor.

Another possibility in this area is a giant follicular lymphoma. We see a few cases with durations as long or very nearly as long as this, and these tumors are prone to arise in the retroperitoneal tissues.

MEDICAL CARE FOR VETERANS

AT LONG last the labors of the special committee created by the Council of the Massachusetts Medical Society to deal with the medical care of veterans seem about to bear fruit. Published elsewhere in this issue of the *Journal* is the new contract, acceptable to both the Society and the Veterans Administration, under which the members of the Society who wish to participate may do so under a so-called "gentlemen's agreement."

The efforts to achieve this end have been involved rather than long in point of time. At its meeting on February 6, 1946, the Council, at the request of General Hawley, appointed a special committee to deal with the problem of the medical care of veterans and their dependents. Two plans were in

existence at that time. The plan in operation in Michigan represented an example of the first. Under this plan the Michigan Medical Service acted as agent, paying the doctors according to an accepted fee schedule, and collecting from the Veterans Administration. According to the second—the Kansas plan—the state medical society submitted to the Veterans Administration a list of members who wished to work under an established fee schedule according to a "gentlemen's agreement."

The committee agreed on the first type of plan for Massachusetts, and it was adopted at a special meeting of the Council on April 10, the Blue Shield to act as intermediary agent. The Executive Committee of the Council was empowered to give final approval to any contract involving the Massachusetts Medical Society, and a fee schedule drawn up by the committee was accepted at that meeting.

At the October 2 meeting of the Council, the report of the committee indicated that in order to co-operate with the Veterans Administration the Society must differentiate specialists and non-specialists. This had never been done, but after much discussion the Council swallowed hard and agreed that specialists could be named "for the purposes of the Veterans Administration only."

The Executive Committee, at the same meeting, recommended that the Council rescind the vote designating the Blue Shield as administrative agent for a veterans' medical-care plan in Massachusetts, on account of certain distressing difficulties encountered in New Jersey. The whole matter, however, was tabled, and the plan as agreed on was continued up to the moment of the Executive Committee meeting of April 23, 1947. Since it was then made apparent that the Blue Shield had failed to obtain necessary legislative approval for the contract, the whole matter was reopened, and at the meeting of the Council on May 19, the committee was instructed to enter into negotiations with the Veterans Administration for a contract along the lines of the Kansas plan. It is this new contract that is presented elsewhere for perusal.

According to this plan, briefly, the Society requests its members to participate in a program whereby physicians in private practice in the Commonwealth will render medical services in such

cases as may be authorized by the Veterans Administration. Fees will be paid to the physician by the Veterans Administration according to an established fee schedule, although no physician will be permitted to accept fee-basis cases in excess of a total compensation of \$6000 in any one year without prior approval of the Administration.

The Massachusetts Medical Society will submit lists of participating members, properly broken down according to geographic distribution, and will assist the Veterans Administration in establishing a list of competent specialists who meet the qualifications of a specialist according to the regulation of the Administration.

Let us hope that this new plan will meet with the success merited by the hard work that Dr Humphrey L. McCarthy and his committee have put into it.

PEDIATRIC SURVEY FIRST FRUITS

THE countrywide study of child-health services inaugurated by the American Academy of Pediatrics in 1944 and now entering on its last lap has been truly a pioneer effort. Never before has a great division of medical practice sought objectively to analyze its own beliefs and its prejudices, its achievements and its failures, and its opportunities. If, in the final analysis, this effort seems to have been productive, others will surely follow.

One thing is certain. This survey cannot be compared to a grand spring housecleaning, where the windows are washed and the corners swept and then the brooms are put away in the closet. It is the setting in motion of a train of constructive ideas, of which those of permanent value will be put into operation at different times and in different places according to local needs and to the degree of local progressiveness. If this study has been soundly conducted, — and of that there is every reason to be certain, — its data will continue to be studied and its recommendations adopted a dozen years from now.

The study in Massachusetts has been completed, thanks to the untiring efforts of the state chairman, Dr James M. Baty. The figures, which were obtained as a result of a high degree of professional co-operation, will not be correlated and published,

however, until late in the fall. One deduction seems justified even at this early date and might be entertained as a provisional conclusion. It is too early for an accurate analysis of the hospital facilities within the Commonwealth, but it seems apparent that existing pediatric beds in many of the small community hospitals are not being economically utilized. There is a tendency for them to be filled at times, as during the tonsillectomy season, and to lie idle at other times, even while ambulances scream on occasion past their doors at considerable risk to both passengers and traffic, carrying patients to crowded pediatric centers in distant cities. This waste of facilities results from a lack both of trained pediatric personnel and of equipment. Given a local practitioner trained in pediatric care, however, and he will see to it that the equipment is eventually forthcoming and that the number of patients who have to be taken for a ride will reach an irreducible minimum.

Centralization has about reached its effective peak, and it is time to pay more attention to developing a self-contained community service. In this development the chief need is for pediatrically trained physicians in these communities. Time was when the specialist in the city counted as one of his activities the care of his consultation practice in the surrounding countryside. Then came the day of the screaming ambulance. We are now entering the more satisfactory era of the well equipped, well staffed community hospital where all but the most unusual cases can receive adequate care.

MASSACHUSETTS MEDICAL SOCIETY COMMITTEE TO CONFER WITH GENERAL HAWLEY

The attention of Society members is called to the following contract recently approved by the Veterans Administration and the Committee to Confer with General Hawley of the Massachusetts Medical Society:

The Massachusetts Medical Society and the Veterans Administration, for the purpose of establishing and maintaining a close working relationship in order to establish a well integrated service for providing medical care and treatment for veterans of the State of Massachusetts beyond those services available to the Veterans Administration in existing Veterans Administration facilities and installations, do hereby mutually agree as follows:

- (1) The Massachusetts Medical Society will request all of its members to participate in a state-wide program whereby physicians in private practice in the State of Massachusetts will render medical services (examinations, treatments and counsel) in such cases as may be specifically authorized by the Veterans Administration
- (2) The Massachusetts Medical Society will submit to the Veterans Administration a list of its members who desire to provide service for eligible veterans in the home communities of such veterans. This list may be augmented from time to time as additional physicians may indicate a desire to participate in the program. The physicians so listed will be fee-basis physicians of the Veterans Administration. By notice in writing a physician may at any time request that his name be removed from the list of fee-basis physicians
- (3) The Massachusetts Medical Society will assist the Veterans Administration in establishing for examinations and treatment, a list of competent specialists who meet the qualifications of specialists of the Veterans Administration
- (4) Lists of physicians submitted by the Massachusetts Medical Society will be broken down by counties or districts in order that the veterans for whom services are authorized may select a physician practicing in his home community. The choice of the physician by the veteran provided for herein, is not applicable to examinations for pension or compensation rating purposes. Such examinations may be performed only by a physician specifically designated for that purpose by the Veterans Administration
- (5) Fees for medical services in authorized cases shall be paid by the Veterans Administration to the physician rendering the service in accordance with the fee schedule hereto attached which is made a part of this agreement. The Massachusetts Medical Society warrants that the rates set forth herein are not in excess of the rate of fees charged other persons who are not Veterans Administration beneficiaries for the same or comparable services. It is mutually understood that the fees stated in the fee schedule represent the maximum amount that may be charged, and do not represent the amount to be paid in every case. The Veterans Administration will advise each physician of this provision and will require each physician to certify in submitting his statement of account that the fees charged are not in excess of the fees charged by him for comparable service rendered nonveterans. It is understood that unusually involved cases and services not scheduled will be subject to review and recommendation by the Massachusetts Medical Society to the Veterans Administration for determination of the appropriate fee.
- (6) The Veterans Administration will handle administrative and clerical details in connection with the authorization of examinations or treatment and the maintenance of records and will arrange for transportation of the veteran if necessary
- (7) When authorizing treatment, the Veterans Administration will furnish to the veteran proof of such authorization and a list of fee basis physicians in the county or district in which the veteran is located in order that he may select his own physician for the services authorized
- (8) The Veterans Administration will review reports of examinations and services to determine their adequacy. No fees will be paid by the Veterans Administration for reports which are not acceptable to the Veterans Administration or for services rendered in unauthorized cases.
- (9) The Massachusetts Medical Society will establish one or more boards of review composed of physicians. It shall be the duty of such board to review reports which are deemed by the Veterans Administration to be inadequate or which do not

meet the requirements of the Veterans Administration to recommend at its discretion the disqualification of any physician for further work with the Veterans Administration whose work is found by the board to be incomplete or unsatisfactory, to advise and assist the Veterans Administration on other matters within the scope of this program

- (10) It is agreed that services furnished under the agreement will be performed by licensed physicians. It is further agreed that physicians rendering services hereunder will be citizens of the United States who are doctors of medicine duly licensed to practice medicine and surgery in the State of Massachusetts
- (11) This agreement shall be effective from July 1, 1947 to July 1, 1948, and may be terminated by either party by giving thirty days written notice to that effect.
- (12) This agreement, if mutually satisfactory, may be renewed indefinitely for a period of one year each, upon notice in writing to the Massachusetts Medical Society at least sixty days prior to the expiration of each period of one year and written statement from the Massachusetts Medical Society within thirty days after such notification agreeing to the renewal.
- (13) No member of or delegate to Congress or resident commissioner shall be admitted to any share or part of this agreement or to any benefit that may arise therefrom unless it be made with a corporation for its general benefit.
- (14) The Massachusetts Medical Society agrees that in performing this agreement it will not discriminate against any employee or applicant for employment because of race, creed, color or national origin
- (15) The Massachusetts Medical Society does not propose to make any charge for any service rendered to the Veterans Administration under this agreement.

In his letter accompanying this contract, General Hawley advised that it had been found necessary to adopt a policy that no physician will be permitted to accept fee-basis cases for the Veterans Administration in excess of \$6000 in any one year without the prior approval of the Administration and that all branch medical directors had been instructed to enforce this policy and to advise all participating physicians that it is in effect.

He also called attention to the fact that in the paragraph providing that physicians shall be licensed a provision had been added that they must be citizens of the United States, as required by law.

He concluded with the statement that it was understood that the Massachusetts Medical Society had agreed to accept the new *Veterans Administration Fee Schedule* (Form 10-2535a), which was attached to and made a part of the agreement.

HUMPHREY L. MCCARTHY, *Chairman*

SECRETARY'S OFFICE

Attention should be called to the fact that a Boston physician's secretary was recently persuaded to advance money to a person posing as Dr. Stanley Rathbun, a cardiologist from New York City, who was temporarily out of funds after a professional trip to Boston. He claimed to be a friend of the secretary's employer, knowing him through

the New York Polyclinic and the Academy of Medicine. He is about five feet, eight inches tall and fifty-five to sixty years old and has dark hair that is on the thinnish side, at the time he was well dressed in a dark-brown suit. He is well versed in medical terminology, especially concerning the heart, and is quite garrulous. It was subsequently learned that he had given a false New York address and was not connected with the Polyclinic.

JOSEPH GARLAND

DEATHS

GRADY — Henry M. Grady, M.D., of Dedham, died on July 30. He was in his seventy-third year.

Dr. Grady received his degree from Harvard Medical School in 1905. He was town physician in Dedham for thirty-two years until his retirement two years ago.

Three brothers and two sisters survive.

HARRIS — Charles E. Harris, M.D., of Hyannis, died on May 21. He was in his seventy-ninth year.

Dr. Harris received his degree from Baltimore Medical College in 1897. He was a former president of the Barnstable District Medical Society.

His widow, two daughters and a son survive.

HENNESSEY — Thomas F. Hennessey, M.D., of Swampscott, died on July 21. He was in his sixty-first year.

Dr. Hennessey received his degree from Tufts College Medical School in 1911. He was a member of the American Congress of Physiotherapy and a fellow of the American Medical Association.

His widow survives.

MEDICOLEGAL ABSTRACT

Liability for Malpractice. Refusal to attend patient without sufficient information regarding symptoms. A recent New Hampshire decision illustrates the danger of a physician relying on a statement of a patient's symptoms given him over the telephone without eliciting adequate information. The patient, a pregnant woman, had begun to flow toward the end of the fifth month of pregnancy and remained in bed for the following two days on the doctor's advice. On the fourth day the flowing had practically stopped. On the sixth day she awoke in pain. According to her evidence her husband called the physician twice during the morning, saying that she complained of severe pains and asking him to come over. This was apparently the first child for the couple, and neither of them recognized the pains as labor pains, which, in fact, they were, so that, of course, the husband did not tell the physician that his wife was having labor pains. After a third call from the husband, in which he reported that a premature birth, referred to in the opinion as "miscarriage," had taken place on the toilet, the doctor came.

The court held that it was for the jury to determine "whether the defendant gave proper consideration to what he knew about the plaintiff's case, whether he used due care in eliciting information from the husband at the times of the first two telephone calls, if they occurred, that would have informed him that the plaintiff was in labor and

whether he was negligent in not attending the plaintiff before she had gone to the toilet and the birth had taken place." The court did not say that the failure of a physician to attend his patient simply because he is asked to is negligent, but recognized that under some circumstances a doctor may be under a duty to ask enough questions to obtain the information required to determine whether or not he is needed.

The court held that the plaintiff was not entitled to any damages for the mere fact of the premature birth, which would have occurred anyway, or for the physical and mental suffering that she would have endured under the usual circumstances that would have accompanied the premature birth, but that she was entitled to damages for the suffering that would have been avoided if the physician had been in attendance. The court pointed out that the child would have been born in bed, and that narcotics and other medicines could have been prescribed to relieve the pain and other care given. The court apparently considered that if the patient was improperly deprived of the doctor's attendance, she was entitled to damages for the loss of the "comfort" of his "assuring presence" and that she was entitled to damages for her "injured feelings attending the happening of the birth in the way it did." (*Michigan v. S—*, N H 51 A [2d] 632)

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

ELECTIVE TONSILLECTOMIES DURING THE POLIOMYELITIS SEASON

Attention was recently called in this column to the advisability of scheduling as many elective tonsillectomies before August 1 as possible, it being noted that after that date further operations would depend on the prevalence of poliomyelitis in the vicinity.

Late in July cases of poliomyelitis began to appear with some regularity in the Metropolitan Area, which marked a warning that the seasonal upswing was imminent. It therefore appears wise to cease scheduling elective tonsillectomies in this area. On the other hand, only three cases of the disease were reported during June and July west of the Metropolitan Area. This indicates that it is safe to continue operations in the western part of the Commonwealth pending an increase in that area. During the same period no case of the disease occurred in the Merrimack Valley, and the same conclusion is warranted.

By the time this note appears in print the situation may have changed considerably in one or both of these areas. All local boards of health and various other agencies receive weekly information regarding the prevalence of poliomyelitis, and the continuance of elective tonsillectomies should be governed accordingly.

COMMUNICABLE DISEASES IN
MASSACHUSETTS FOR JUNE, 1947

RÉSUMÉ

DISEASE	JUNE 1947	JUNE 1946	SEVEN YEAR MEDIAN
Chancroid	1	1	1*
Chicken pox	182	1400	1267
Diphtheria	3	21	11
Dog bite	1472	1318	1266
Dysentery bacillary	11	2	2
German measles	90	57	535
Gonorrhea	316	326	355
Granuloma inguinale	0	1	0*
Lymphogranuloma venereum	0	1	0*

*Three-year median

†Five-year median

COMMENT

The diseases above the seven year median are chicken pox diphtheria dog bite, bacillary dysentery Pfeiffer bacillus meningitis pulmonary tuberculosis and tuberculosis, other forms and undulant fever.

The diseases below the seven year median are gonorrhea malaria, meningococcal meningitis mumps salmonellosis syphilis and whooping cough. Considerably below the seven year median are German measles measles lobar pneumonia, scarlet fever and typhoid fever.

Only two cases of poliomyelitis were reported.

Diphtheria did not show such a marked seasonal decline as would be desired. The number of cases reported did not decrease appreciably from the levels of the two preceding months.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Diphtheria was reported from: Avon 1 Barnstable, 1 Beverly, 1 Billerica 1 Boston, 9 Chelsea 6, Lynn 1 Waltham, 1; Reverse 11, Somerville 3 Waltham 1 Water town 1 total 37.

Dysentery amebic, was reported from Fall River 1 total 1.

Dysentery bacillary, was reported from Marblehead 1 Worcester (State Hospital), 10 total 11.

Lymphocytic choriomeningitis was reported from Cambridge, 1, total, 1.

Malaria was reported from Boston 3 Lawrence 1 Waltham 1 Monmouth 1 Winthrop 1 Worcester 1 total 8.

Meningitis meningococcal, was reported from Boston, 1 Oxford, 1 Quincy 1 total, 3.

Meningitis, Pfeiffer bacillus was reported from Brockton, 2 Concord, 1 Oxford 1 total 4.

Meningitis pneumococcal, was reported from Framingham 1 Lexington 1 Waltham, 1 total 3.

Meningitis, other forms was reported from Boston 2 total 2.

Meningitis undetermined, was reported from Malden 1 total 1.

Poliomyelitis was reported from Boylston 1 Springfield 1, total 2.

Salmonellosis was reported from Boston, 3 Lawrence, 1 Lynn 1 Newton, 1 Worcester 1; total, 7.

Septic sore throat was reported from Boston 4 Easthampton 1 Greenfield 1 Merrimack 1 total 7.

Tetanus was reported from Boston 1, Springfield, 1 total, 2.

Trichinosis was reported from Boston 1 Waltham 1 total, 2.

Undulant fever was reported from Brookline 1 Lancaster, 1 Milford 1 Worcester 13 total, 16.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

The Complete Pediatrician. Practical, diagnostic, therapeutic and preventive pediatrics. By Wilburt C. Davison, D.Sc. M.D. professor of pediatrics, Duke University School of Medicine, and pediatrician Duke Hospital. Fifth edition. 8° cloth 354 pp. Durham North Carolina: Duke University Press, 1946. \$4.00.

This unique manual has proved popular and useful as a ready reference source for all physicians and students called on to care for sick and healthy children. The whole field of pediatrics is covered in two hundred and fifty six topics of varying length. The material is arranged in thirteen chapters according to diseases of the body systems, to which are added laboratory procedures nutrition and feeding general and physical therapy and nursing growth and development and drugs and prescriptions. An ingenious system of cross reference from one topic to another makes readily available all information on a given subject contained in the volume. A comprehensive index completes the book. Emphasis is placed on diagnosis and treatment. In the laboratory section two hundred and two of the best practical methods are described. This manual contains a wealth of condensed information and should prove useful to all physicians.

The Problem of Fertility. Proceedings of the Conference on Fertility held under the auspices of the National Committee on Maternal Health. Edited by Karl T. Engle. 8° cloth 254 pp., with 28 illustrations. Princeton: Princeton University Press 1946. \$3.75.

Nineteen leaders in research in the field of fertility read papers at the Conference on Fertility held in February 1946, at Princeton University, and these articles are brought together in this volume. The articles summarize the research done on domesticated animals and on man. The participants were animal husbandrymen and clinical researchers who met probably for the first time in a joint conference, to discuss a topic of mutual interest.

The points covered in the discussions include the relation of fertility to the time of ovulation the effect of the condition of the cervical mucus and the viability motility and fertilizing capacity of spermatozoa. Consideration was given to human fertility as well as to that of laboratory and domesticated animals. Pertinent bibliographies are attached to the articles. The volume is well published. It is recommended for all medical libraries as a reference book.

Preoperative and Postoperative Treatment. Edited by Lieutenant Colonel Robert L. Mason, M.C., A.U.S., Cushing General Hospital and Harold L. Zintel, M.D., Harrison Department of Surgical Research University of Pennsylvania School of Medicine and assistant surgeon, Hospital of the University of Pennsylvania. Second edition. 8° cloth 584 pp., with 157 illustrations. Philadelphia: W. B. Saunders Company 1946. \$7.00.

This composite work of twenty collaborators has been revised to include the important advances in surgery occurring since the publication of the first edition in 1937. The type has been completely reset and nearly every chapter has been rewritten. The following new material has been added: physical medicine in surgical practice preoperative and postoperative care in gynecology and surgery of the stomach and duodenum intestinal obstruction nutrition in surgery, surgical risk in pregnancy thrombophlebitis vitamin K therapy and emergency care in cranial injuries. A selective bibliography is appended to each chapter and the text is printed with a good type on heavy coated paper, resulting in a volume that is much too heavy for its size. This book is in all medical libraries and in the libraries of

Henry Sewall Physiologist and physician By Gerald B Webb and Desmond Powell 8°, cloth, 191 pp., with 10 plates Baltimore Johns Hopkins Press, 1946 \$2.75

This is a well written biography of an eminent American physician and scientist. Educated at Wesleyan and Johns Hopkins universities, he studied abroad and on his return to the United States became an assistant in physiology at Johns Hopkins University School of Medicine and, in 1882, professor of physiology at the University of Michigan. Afflicted with tuberculosis, Sewall went to Colorado in 1888 and, after doing some work in medicine, was given an M.D. degree by the University of Denver. In 1889, because of his disease, he became a resident physician at the Trudeau Sanatorium at Saranac Lake, remained there a short time, and then began to practice in the near-by town of Lake Placid. In 1890 he went to Denver to remain permanently, practicing medicine and serving on the Board of Health and on the faculty of the University of Denver as professor of physiology, he was also professor of medicine at the University of Colorado Medical School. He became eminent as a physician, specializing in tuberculosis, and was elected a member of the Association of American Physicians in 1900, the highest medical honor of its time. He was elected president in 1916. He died at his home in Denver on July 8, 1936. A bibliography of the writings of Dr. Sewall and an index conclude the volume. This delightful biography is well published and should be in all medical libraries and medical-history collections.

Clinical Hematology By Maxwell M. Wintrobe, M.D., Ph.D., professor of medicine, University of Utah School of Medicine. Second edition, thoroughly revised. 8°, cloth, 862 pp., with 197 illustrations and 14 plates, 10 in color. Philadelphia Lea and Febiger, 1946 \$11.00

This standard textbook on its subject has been thoroughly revised and brought up to date. The book, which is well published, is recommended for all medical libraries and should prove useful to physicians interested in diseases of the blood.

Yearbook of Psychoanalysis Volume II, 8°, cloth, 280 pp. New York International Universities Press, 1946 \$7.50

The second volume of this annual contains fourteen articles by recognized authorities in the field of psychoanalysis reprinted from various publications of 1945, some of which are relatively inaccessible. The publication in one volume brings them together for ready reference. The yearbook is recommended for all medical and psychiatric libraries.

X-Ray Diffraction Studies in Biology and Medicine By Mona Spiegel-Adolf, M.D., professor of colloid chemistry and head, Department of Colloid Chemistry, Temple University School of Medicine, and George C. Henry, M.D., professor of medical physics, Temple University School of Medicine. 8°, cloth, 215 pp., with 87 illustrations. New York Grune and Stratton, 1947 \$5.50

Monographs on this difficult subject have been written for the physicist and chemist, but this is the first discussion in English for the biologist and research physician. Purely physical and mathematical discussions have been omitted wherever possible. The text comprises a survey of the literature of the subject combined with the studies of the authors carried on during the past ten years. The beginning chapters discuss the theory, apparatus and technique and interpretation of x-ray diffraction patterns. Special chapters are devoted to the biologic substances, including carbohydrates, amino acids, proteins, nucleic acids and nucleoproteins, lipids and steroids, and to muscle, nerves, bones, teeth and concretions. The chapter on the proteins is comparatively large, owing to the amount of work done in this field. To each chapter is appended a list of selected references. Author and subject indexes conclude the volume, which is well published in every way. The work should be in all medical reference collections and in all biologic laboratories.

Physical Medicine in General Practice Edited by Arthur L. Watkins, M.D., 8°, cloth, 341 pp., with 15 illustrations. Philadelphia J. B. Lippincott Company, 1946 \$5.00

This symposium by fourteen specialists, originally published in *Clinics*, is brought together for the benefit of practicing physicians. The fields of medicine, surgery and the various specialties in which physical therapy has proved of value are well covered. The articles on rehabilitation and employment, and on reconditioning in some Army hospitals are particularly timely. There are special articles on fever therapy and chemotherapy and on the use of cold in medicine and surgery. To each article is appended a list of references to recent literature. The articles are concise and well written. The volume is well published and should prove useful to the practicing physician.

NOTICES

MEDICOLEGAL CONFERENCE AND SEMINAR FOR PATHOLOGISTS, MEDICAL EXAMINERS AND CORONERS

Beginning on Monday, October 13, the departments of legal medicine of the medical schools of Harvard, Tufts and Boston University, in association with the Massachusetts Medico-Legal Society, will present at Harvard Medical School a six-day program of lectures, conferences and demonstrations having to do with the investigation of deaths in the interests of public safety. Attendance will be limited to twenty-five persons who have registered in advance. Further information may be obtained from the Department of Legal Medicine, 25 Shattuck Street, Boston.

NORFOLK DISTRICT MEDICAL SOCIETY

The Norfolk District Medical Society will hold its 1947-1948 meetings at the Boston Medical Library, 8 Fenway, Boston. The meetings will start at 8 p.m. Detailed notices of all meetings will appear at later dates.

Tuesday	September 23	Boston University Night
Tuesday	October 28	Lahey Clinic Night
Tuesday	November 25	Tufts Night
Tuesday	January 27	Round-Table Discussion Bleeding from the Alimentary Tract
Tuesday	February 24	Obstetric and Gynecologic Night
Tuesday	March 23	Harvard Night

Collations will be served

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY

At the annual meeting of the American Board of Obstetrics and Gynecology, held in Pittsburgh from June 1 to 7, a number of changes in regulations and requirements were put into effect. Among these is the new ruling that the Board does not subscribe to any hospital or medical school rule that certification is to be required for medical appointments in rank lower than chief or senior staff of hospitals or associate professorship in schools of medicine, for the obvious reason that such appointments constitute desirable specialist training. At this meeting the Board also ruled that credit for graduate courses in the basic sciences that involve laboratory and didactic teaching rather than clinical experience or opportunities will be given credit for the time spent up to a maximum period of not more than six months, regardless of the duration of the course.

The next written examination (Part I) for all candidates will be held in various cities of the United States and Canada on Friday, February 6, 1948, at 2:00 p.m. Applications are now being received for these examinations, and the closing date for the applications is November 1. Further information and application blanks may be obtained from Paul Titus, M.D., Secretary, 1015 Highland Building, Pittsburgh 6.

SPECIFIC READING DISABILITY*

A Familial Syndrome Associated with Ambidexterity and Speech Defects and a Frequent Cause of Problem Behavior

RICHARD S. EUSTIS, M.D.†

BOSTON

CHILDREN who have not learned to read or to read fluently and with understanding are almost disgracefully numerous in our schools. Educational literature gives no clear picture of why this is so. The list of reasons advanced for their failure is a long one and includes such items as low intelligence, physical illness, malnutrition, visual and auditory defects, immaturity, lack of interest, emotional blocking and poor teaching. The viewpoint of the majority of teachers and child psychologists is clearly expressed by Witty and Kopel,¹ who, after full discussion of the various causes, state emphatically that there is no single specific cause, but that causation must be sought in a composite of related conditions.

On the other hand, physicians²⁻⁵ and a few educators⁶⁻¹² maintain that buried in the amorphous mass of children who fail for a multiplicity of reasons—physical, mental, psychologic and social—is a hard kernel of children of a distinctive type. They are predominantly boys whose weakness in the use of language¹³ is definitely out of keeping with their skills in other directions, particularly in arithmetic. Many are late in learning to talk and, when they do talk, are likely to lisp or stutter. They are apt to be more or less ambidextrous. Their family trees, when accurate histories are obtainable, are found to contain a large number of similar persons. When such children are studied, it becomes clear that in this restricted group there does exist a single factor that plays a large part in their reading difficulties. This factor is believed to be an inherited sex-associated weakness of the language function combined with a tendency to ambidexterity. The name given to this syndrome is "specific language disability." When the difficulty is chiefly with reading,

it is called "specific reading disability" or "strophosymbolia" (Orton¹⁴).

This disagreement between educators and psychologists on the one hand and physicians on the other would be of no practical import were it not for the fact that most schools fail to separate children with specific reading disability from other poor readers. The result is often tragic failure for the children with the specific disability.

This is a report on 23 carefully studied children with specific reading disability. They were selected from a larger group of 33 who were examined because of school failure or problem behavior. For the 10 children eliminated from the group the diagnoses were encephalitis, low I.Q., hypothyroidism, poor teaching and poor discipline.

MATERIAL AND METHODS

The children in this group were followed for an average of eight years—some for as few as two years, and others for as many as sixteen. All were private patients coming from twenty-one families. The status of all but one of the homes was known. Two could be classed as high average, and the others as definitely superior. The occupations of the fathers were as follows: business, 9; university professor, 7 (4 of these were physicians); professional, 3; gentleman farmer, 1; and clerical, 1.

Seventeen children attended private schools of excellent reputation. Six had started in public school in good residential districts, but 5 of them, when their difficulties were recognized, changed permanently or temporarily to selected private schools where individual tutoring could be supplied.

These 23 children were in normal physical condition except for one with hemiplegia. The vision of 20 either was normal or had been corrected by glasses. Three had defective vision in one eye only, their hearing was normal. Psychometric tests

children's Medical Service, Massachusetts General Hospital.
‡Language is an inclusive term for speech, reading, writing.

(Stanford-Binet) on 17 gave results ranging from an IQ of 85 to one of 136. The true levels were probably a few points higher, since it is generally admitted that children with specific reading disability are handicapped in certain of the tests. There were only 5 with levels below 100, and their performance was judged according to their mental ages. Because their parents opposed it, 6 were not tested, but these children were well known by the examiner, who considered their intelligence to be at least normal.

The group were given standardized scholastic achievement tests that graded skill in arithmetic,

defects or difficulty in reading and spelling. Here the examiner's knowledge of the family was a great help in uncovering otherwise forgotten details. A note was also made of any unusual behavior on the part of the children.

Young infants are equally clumsy with both hands and should therefore be described as ambilateral instead of ambidextrous. By the end of the second year, one hand has usually been chosen more and more for skilled activities,* and habitual use strengthens and confirms the selection. The majority believe that handedness is determined by Mendelian inheritance,^{3, 4, 13} although Blau¹⁴ argues

silent reading, oral reading, reading speed and spelling. All made scores in arithmetic that corresponded approximately to the mental age. In their reading and spelling skills, however, they were from one to three or even four grades behind. They either were unable to read or read slowly and without much understanding. Frequently, they failed to recognize simple words and tended to confuse such letters as "b" and "d," and to reverse short words such as "on" for "no" and "was" for "saw" or syllables such as "astrep" for "repast." The handwritings were, in general, poor, and the spelling was worse. Because of this specific failure in reading, which was out of all proportion to their skill in other lines, these children were classed as cases of specific reading disability.

They were also tested to determine the leading hand and eye. Note was made of any defect in speech. The parents were questioned on previous defects in speech or delay in learning to talk, as well as on a family history of other members who were left-handed or ambidextrous or who had speech

that most people are right-handed because of social and cultural pressure and the minority left-handed because they were strongly negativistic in early childhood. According to the inheritance theory, since mankind is of mixed stock (heterozygous) so far as handedness is concerned, the offspring present a series of intergrades between a few strong dextrals at one end and few strong sinistrals at the other. Practically, however, the race is predominantly right-handed, and has been so since the Bronze Age,¹¹ although nobody knows why. It seems evident that the pressure of existence in this right-handed world shifts most of the intergrades toward the right.

Laterality tests are used to determine approximately where in this series of intergrades the subject should be placed — that is, whether his handedness is right, right with some left, left with some right or left. Questioning or observation while the subject is performing trained activities such as writing gives results heavily in favor of the right hand.

*Cobb¹² and Blau¹⁴ have presented studies on the relation between handedness and language.

A battery of tests completed while the subject is in ignorance of the examiner's purpose gives a truer picture and usually shows more evidence of partial ambidexterity. The amount of ambidexterity reported varies with the author's definition of the term and the technic used in testing. The consensus seems to be that at least 75 per cent of school children and adults are right-handed and 25 per cent either left-handed or partly ambidextrous.¹²⁻¹⁴

In these tests the children were asked to use a few simple tools, such as a hammer, screw driver and scissors, and to play a xylophone, throw a ball, swing a bat, wind a watch, wind up a ball of string,

FINDINGS

Table 1 presents the sex, age and presenting complaints of these children, as well as their preferences of hand and eye, degrees of specific reading disability, I Q's, the presence of speech defects or of delay in learning to speak, the existence of similar conditions in the family history and, finally, the type, duration and result of treatment.

Handedness

The hand originally preferred by one boy (Case 12) could not be determined because of hemiplegia. Of the remaining patients only 4 were right-handed,

‡Patient had hemiplegia

play cards, pick up cards dropped on the floor and, finally, write their names and a short sentence. If the subject showed evidence of being partly ambidextrous, he was then asked to write with his non-preferred hand, and the two signatures were compared. The results were scored as right, right with some left, left with some right and left.

To determine eye preference a few equally simple tests were used, such as asking the subject what he saw through a kaleidoscope, the examiner meanwhile noting which eye was used, having him identify an object held in front of the examiner's face while he was looking through an open cone whose large end covered both eyes, having him look through a small hole, and finally, having him point at the examiner first with the forefinger of one hand, then with the forefinger of the other and lastly with a pencil held simultaneously in both hands. The only precaution needed was to be sure there was no serious visual defect in either eye. The results were scored with the use of the same scale as in the hand tests.

18 were more or less ambidextrous, and none were left-handed. Eleven of the ambidextrous were right-handed with some left-handed skills. They considered themselves, and on casual observation would be classed as, right-handed. Seven of the ambidextrous were left-handed with some right-handed skills and would similarly be classed as left-handed. Thus, although from questioning or simple observation, 15 of the 22 subjects, or two thirds, would be considered right-handed and 7, or one third, left-handed — a ratio that is approximately the same as that of the general population¹²⁻¹⁴ — the truer proportion was only one fifth right-handed, with four fifths more or less ambidextrous and none purely left-handed.

This great preponderance of ambidexterity is in accordance with the reports of physicians⁶⁻⁹ on handedness in cases of specific reading disability. It is in great contrast to the reports by psychologists and educators, most of whom found no more left-handedness and ambidexterity in poor than in good readers.¹ It is also in great contrast to the generally

accepted standards of handedness in the general population¹³⁻¹⁵ Finally, it strongly supports the theory that lack of clear manual dominance is closely associated with specific reading disability

This discrepancy between the results obtained by psychologists and educators on the one hand and neurologists on the other — followers of different although somewhat related disciplines — can only be explained by the assumption that identical groups have not been studied or that different methods and standards are used in the tests Therefore, instead of disputing each others' findings and conclusions, both groups should try to define more accurately the group that they are testing and to describe more clearly just how the tests on laterality are conducted and recorded

Eyedness

Three children had defective vision in the right eye* Of the remainder 11 sighted with the right eye, and 4 with the left eye, and 5 were amblyopic — 2 with a preference for the right eye, and 3 for the left Seven showed "crossed laterality" in that the eye preferred for sighting was on the opposite side from the preferred hand One of these was right-handed and left-eyed The others were partly ambidextrous 3, preferring the right hand for most acts, sighted usually or entirely with the left eye, and 3, preferring the left hand, were right-eyed

The significance of these figures on eyedness is not clear There is certainly no such predominance of amblyopia in these children as there is of ambidexterity, and the number with crossed laterality is apparently no greater than that in normal children¹⁵

Family Histories

In hospital clinics, and presumably in schools as well, it is difficult to obtain satisfactory family histories of delay in learning to talk, speech defects, ambidexterity and reading disability The pediatrician in private practice has a far better opportunity to obtain them because he has been in the homes and is more or less acquainted with other members of the family

In this series of cases of specific reading disability, there was a history of left-handedness or ambidexterity or of one of the above-mentioned forms of language disability in 18 of the 21 families (85 per cent) in which the information was asked for and recorded This high incidence and particularly the study of some of the individual family trees afforded strong evidence that the trait resulting in these conditions is inherited

Effect on Behavior

Frustration is now recognized as one of the underlying causes of problem behavior such as showing off, lying, stealing, arson or withdrawal from the

group into solitude, as well as of complaints of a more medical nature, such as enuresis, indigestion and obesity Certainly, these children were seriously frustrated by their school failure, and it is interesting that the records of only 10 make no mention of unusual behavior or illness

Five children were solitary and comparatively friendless, 2 were obese from simple overeating 2 lied habitually, 2 stole habitually, 2 were known to masturbate (1 of these had sexual relations with his sister and also undressed before a mixed group of children), 1 terrified his parents by threatening to run away, 1 set the barn on fire, 2 had indefinite illnesses associated with school tests, and 1 with an I Q of 120, who managed to control himself at the time, has since admitted that at the age of twelve and a half he felt sure that he was a "moron" One of the obese children and 1 sex offender came from broken homes — a fact that was undoubtedly partly responsible for their behavior

TREATMENT†

The diagnosis of specific reading disability means that the patient's poor schoolwork and problem behavior are due to the way he is made and to the manner in which his brain and nervous system function, not to laziness, stupidity, lack of interest, poor concentration or any physical ailment or abnormality Quite literally, he is unable to learn reading the way it has been presented to him but can learn although slowly, if a different approach is used

The basic difficulty with these children seems to be that for part of the time, but only for part of the time, they try to read from right to left A word or a letter read correctly on one line may be read backward in whole or in part on the next line, and the resulting errors make utter nonsense

Therefore, the basic aim in teaching reading and writing to these children is to establish firmly in their minds and fingers the correct left-to-right sequence and the shapes, names and sounds of the letters Because their visual images are uncertain they are helped (as most persons are in memorizing) by kinesthetic reinforcement — that is, by looking at the letter, saying it and writing it simultaneously They are gradually taught to blend the sounds into short words and then into longer words Eventually, as they master reading, they learn to recognize whole words just as those who were taught from the first by the whole-word method do Even after they are reading more or less successfully, the letter drills must be continued to prevent a setback Throughout, the emphasis is on accuracy and understanding rather than on speed, which may not come later according to the interests, aptitudes and opportunities of the children Unless there are other factors in the situation, the short attention span, the emotional blocking and the behavior problems tend to disappear as the child

*It should be noted that specific reading disability may occur in children with monocular vision

†Detailed accounts of treatment have been presented by Orton¹ and by Gillingham and Stillman¹⁰

gains confidence in his ability to learn by this method

The actual treatment is best conducted by a skillful teacher who has enough understanding of child psychology and of the working of the nervous system to know what she is trying to do. The best results are obtained from individual tutoring for a half to one hour, five days a week, for periods of one, two or three years. The length and intensity of the tutoring depends on the intelligence of the child, the severity of his disability and his age. Younger children, other things being equal, respond far more quickly than older ones in whom years of failure have produced well justified discouragement and emotional tensions.

Practical Difficulties

Once the diagnosis has been made and the situation explained to the parents, the physician would like to hand the treatment of his patient over to the school. Unfortunately, this is seldom the best course, and then only for mild cases attending schools with good remedial teachers. Although most schools recognize reading disability and many schools have remedial reading classes, few distinguish cases of specific reading disability from their other poor readers, and fewer still are prepared to supply the intensive individual and long-continued tutoring required for the best results. The classes in remedial reading are overcrowded, and the teachers usually overworked and under constant pressure to return their pupils to the regular classes as soon as possible. The result is that pupils with a mild degree of disability — or even a moderate degree, if their intelligence is high — may learn to read after a fashion, but not well enough to do good work in the upper grades. The severer cases and patients of only average intelligence, if in public schools, are apt to end up in special classes, where they certainly do not belong, and if in private schools, to transfer from school to school in constant hope that a miracle will occur.

Therefore, it is usually necessary to advise individual tutoring by a specially trained teacher. This tutoring is best done at the school during the periods when the rest of the class are working on English so that it will not interfere with the pupil's other studies. Also, since it is not a punishment, it should never be allowed to interfere with the pupil's time off for play. Arranging for this remedial tutoring requires the consent of the school head. Although some headmasters are co-operative, others are not, perhaps through no fault of their own, and it may become necessary to transfer a pupil to some school where the tutoring can be managed.

Results

The patients varied so in their aptitudes, interests and intelligence that it was difficult to establish satisfactory standards for the degree of specific reading disability from which each one suffered and equally difficult to assess the degree of improvement

shown by each as the result of treatment. In general, a child who was retarded one year in reading was classed as a mild case, one two years as a moderate case, and one three or more years as a severe case. It soon became evident, however, that a second grader one year behind in reading was much worse off than a fifth grader one year behind, and consequently the examiner's personal impression and knowledge of the patients were taken into consideration in the classification of each case as mild, moderate or severe. Even so, this grading must be regarded as relative and not absolute.

All the children eventually learned to read — even the two who had little or no real remedial tutoring. For those who are now doing satisfactory school or college work without assistance or have graduated, the result is classed as "good." For those whose disability has seriously affected their education and future livelihood, the result is classed as "poor." Those between the two extremes are classed as "improved."

Good Results

The IQ's of the 16 children who had good results were normal or above, the average for the 10 children who were given psychometric tests being 113.

Remedial work by the school only. All the schools involved had good teachers of remedial reading. Six of the 8 children whom they handled successfully without outside help had mild cases. The duration of the remedial training was one to five years.

In Case 5, in which the disability was moderate, the patient had two years of remedial training and then went to boarding school, where he is doing fairly well.

In Case 9, in which the disability was severe, the patient was bright enough to conceal his disability until he was twelve, and then on a change of schools failed completely. After a year and a half of remedial training at another school with a good remedial teacher, he did well at boarding school but was able to graduate from college only by avoiding reading courses.

These 8 children would surely have made faster progress in learning to read and thereby have avoided a considerable amount of discouragement and attain had they received skilled individual tutoring as soon as their disability was apparent. Such tutoring was urged for most of them but was refused by the parents largely because the school considered it unnecessary.

Remedial work partly by the school and partly by an approved tutor. In this group were 3 mild cases, 2 moderate, and 3 severe. The patients attended schools with good remedial teachers.

The patient in Case 11, whose disability was mild, was doing poorly in a school where he had had no remedial training. He was tutored individually for one summer only and then transferred

to a school whose remedial teacher continued to work with him for three years. He is now doing well at a college preparatory school.

In Case 12, with a mild disability, the patient needed two years of remedial work by the school and two more of individual tutoring before he responded. The slow progress was largely due to the mental and emotional depression associated with his hemiplegia.

In Case 12, in which the disability was mild, the patient failed to learn to read in the early grades and became a behavior problem. He was transferred to another school and given a year of individual tutoring under supervision and another by the school's remedial-reading teacher. At the end of that year he was reading up to his grade level and had become president of his class. His parents then returned him to his original school.

The patient in Case 21, whose disability was moderate, failed to learn any reading in the first half of the first grade and became a serious behavior problem. At the age of six and a half, his parents sent him to a boarding school, where his disability was not recognized until he was tested at the end of his third year. During the next year, the school's remedial teacher worked with him without any improvement. He was then put under an approved tutor in another boarding school with great improvement, and during the next year was taught by the school's remedial teacher, by the end of which time his reading was at his grade level and his behavior much better.

In Case 23, with a moderate disability, the school worked with the patient for three years before they asked for help. She was then given a year of individual tutoring, after which there was no further difficulty.

In Case 16, in which the disability was severe, the patient improved so rapidly after a year of individual tutoring that he needed only one more year by the school. His IQ was probably well above the average.

The patient in Case 18, whose disability was severe, needed two years of individual tutoring and then another after the lapse of one year.

In Case 19, a severe reading disability was recognized early. The school assured the parents that the remedial reading teacher could handle him successfully. He continued to do poorly, and on a teacher's advice was fitted with aniseikonic lenses without benefit. Finally, at ten and a half years, his failure was so obvious and he was so unhappy that he was tested thoroughly and was found to have a severe disability. His arithmetic score was also low, apparently because of his general discouragement. A year of individual tutoring produced great improvement. He then moved away for several years. On his return, he was given a little more individual tutoring and is now, at the age of seventeen, doing fairly well at a small boarding school.

Improvement

One patient is still under treatment, 1 has a low IQ, and 1 received insufficient individual tutoring in view of the severity of his disability.

Remedial work partly by the school and partly by an approved tutor. The patient in Case 22, with a moderate disability, failed to learn to read in one school and was shifted to another, where there was a good remedial-reading teacher. After four years there, her work was still so poor and she was so unhappy that she was tested for the first time. A year of individual tutoring followed by more remedial work in another and smaller school helped immensely. She is still not a good reader, but her present difficulties are due more to the discrepancy between her IQ and those of her associates than to her poor reading. This result is classed as "improvement" rather than "good" because the inadequate handling of her disability is partly responsible for her present unhappiness.

In Case 17, in which the disability was severe, the patient had four years of remedial work in a selected school, and then one year of individual tutoring followed by another year's work by the school. At the age of twenty-one he is in college receiving honor marks in science and passing in English, but failing in the required foreign language.

In Case 20 the disability was severe, the patient was late in talking, had a speech defect and failed to learn to read in the first grade. He is in his third year of individual tutoring, and both his reading and his speech have improved rapidly under phonetic training. This result is classed as "improvement" instead of "good" because the reading is still below grade.

Poor Results

Remedial work by the school only. In Case 1, with a moderate disability, a stuttering, partly ambidextrous, clumsy* boy had a poor start with several changes of school and several years of teaching at home. His stuttering became worse, and finally, at the age of fifteen, he was tested and found to be two years behind in reading and four in spelling. Skilled individual tutoring was advised and refused. The next winter the patient broke his right arm, and while he had to use his left, both his stuttering and his school marks improved. Nevertheless, he refused to continue left-handed writing. He later went to a tutoring school, where he failed completely, and then to a small country boarding school, where he was much happier. He was in the Army for two and a half years. At the age of twenty-three years, the patient is teaching farming at the same small boarding school and is said to stutter only under great stress.

The patient in Case 8, whose disability was moderate, had two and a half years of remedial training in the first, second and third grades before

*Apraxia is often part of the picture

changing schools. He has continued to have trouble with reading and is now failing in a preparatory school.

Remedial work partly by the school and partly by an approved tutor. In Case 13, in which the disability was mild, the patient attended a school without good facilities for remedial reading. He has had only three months of approved individual tutoring. He has also been to a remedial-reading clinic for a few summers, but has received no consistent training through the school years. At the age of fifteen he is failing in a preparatory school. His reading comprehension is above that of his grade, but his reading speed is too slow for him to complete his assignments.

In Case 15 the disability was moderate. The patient failed to learn to read in the early grades. He then transferred to another school and received a year and a half of individual tutoring followed by another in the school's remedial-reading class. In view of his comparatively low I.Q., this was not enough. Nevertheless, instead of continuing the tutoring, his parents chose to make several successive changes of school. At the age of eighteen he is doing poorly and does not expect to try for college.

DISCUSSION

These case histories were obtained from a carefully studied series of private patients, and what they lack in volume they more than make up in accuracy. They point out the difference between the term "reading disability," as used by most educators and psychologists,¹ and the more restricted diagnosis of specific reading disability. They make clear that the latter is a definite entity, occurring in children of all grades of intelligence, although work with those who are below the normal range is scarcely worth while. The histories confirm the opinion that patients can be discovered by means of scholastic achievement and psychometric tests, and that the diagnosis is strengthened by the finding of delayed or defective speech and ambidexterity in the child and in the family tree.

These cases also show that selected schools with good remedial teachers can obtain good results with mild cases of disability with a normal or better I.Q. (Cases 2-4, 6, 7 and 10), fair results in moderate cases with a normal I.Q. (Case 5) and even a good result in a severe case (Case 9), with a high I.Q. Ten cases illustrate the benefit of skilled individual tutoring (Cases 11, 12, 14, 16, 18, 19, 20, 21, 22 and 23), 2 the folly of frequent changes of school and methods (Cases 1 and 15), and 3 the difficulties that patients of good intelligence may have because of insufficient skilled individual tutoring (Cases 8, 13 and 17).

SUMMARY AND CONCLUSIONS

Specific reading disability is a definite entity usually associated with ambidexterity and speech defects both in the patient and in the family tree.

Ambidexterity, left-handedness and speech defects are not causes of specific reading disability. They are merely frequently associated findings and as such are to be regarded as part of the same picture.

Crossed laterality and ambliocularity seem to occur approximately as often in normal children as in children with specific reading disability. They are, therefore, probably neither causes of the disability nor frequently associated findings.

Specific reading disability may occur in children of any degree of intelligence, but intensive treatment is hardly worth while in those who are below the normal range. Unrecognized or inadequately treated, it frequently results in frustration, discouragement and problem behavior. When properly treated, patients with normal to superior intelligence are able to do well in school and college.

Mild cases can be handled successfully by some schools, although they respond more quickly and with less discouragement and problem behavior to skilled individual tutoring. Moderately severe and severe cases need intensive individual tutoring for several years. The older patients, especially, need an interested and understanding physician or psychiatrist to supervise the course of treatment and to encourage them and their parents.

Frequent changes of school or of methods of treatment are of no benefit.

Children who do not learn to read in the first grade should be studied carefully, and if they prove to have specific reading disability, they should be taught to read, write and spell by phonetic and kinesthetic methods.

General practitioners and pediatricians should know enough about the subject to make a provisional diagnosis in cases of specific reading disability that may be brought to them for school failure or problem behavior, and to advise the parents accordingly.

GYNECOLOGY IN THE COMMUNITY*

LEWIS C SCHEFFEY, M D , Sc D (Hon)†

PHILADELPHIA

SOME years ago a colleague of mine in a western city told me that whenever he was asked to speak on the subject of "office gynecology," he refused, because he did not believe that there was such a thing. I heartily disagree with his concept, for I think that the office of the general practitioner is often—but not always—the original source of much good for the patient.

Recently, Thompson and Thompson,¹ of Camden, Arkansas, presented many points worthy of cognizance and reflection, and their paper is recommended to those who have not read it. I acknowledge that it has furnished somewhat of a background for a number of things that I shall present. The authors quote a previous author, DeBakey, as follows: "There are in the United States today some 160,000 practicing physicians, of whom only slightly more than 20,000 are certified by the various specialty boards as qualified in their chosen fields." The import of this fact is that there is approximately 1 certified specialist to 8 general practitioners. Although this does not, of course, take into account part-time specialists or specialists who have not attempted to become certified, it means that the bulk of the population is taken care of, at least primarily, by the general practitioner, whose responsibility is therefore great. He must be prepared not only to recognize the gynecologic lesion that requires the specialist's attention but also to ferret out a host of disorders in every anatomic location that may require further attention by a specialist.

I admire without stint the conscientious and hard-working general practitioner, he amazes me constantly because he knows so many things about so many different regions. Any specialist, if he is not mindful of his thinking, fails to take this into account when he considers some mistake or error in judgment by the family doctor as inexcusable. How much better would he do in a field far removed from his own ivory tower? I am thankful that I am not simply a "career man" in my specialty. I cherish not only the memory of but also the experience gained in a few early years of general practice in a small community, adjacent however to an urban medical center, for this opportunity endowed me with a valuable sense of humility.

Thompson and Thompson draw attention to the fact that apparently more and more patients consider themselves competent to select their own

specialists, without consulting their family physician beforehand, and it is believed that this trend may be intensified because of the experience of war veterans and their families with the huge consultation service available in the medical departments of the armed forces—the concept is gaining ground "that only specialists are competent to treat patients."

The authors also cite Pressley's observation that "80 to 85 per cent of those seeking medical care could be skilfully and successfully cared for by a well-trained general practitioner." Although this statement may be true, it is open to contradiction far too often, as many of us know, when the physician fails to recognize his limitations. Further discussion of why this should happen is a controversial matter and has too many aspects to be covered wisely or completely in a presentation of this sort. Suffice it to say that I have merely mentioned these things as a prologue to my discussion of the part that the general practitioner in the community can take in recognizing and solving what appear to be gynecologic problems, for it is this field that I am expected to be familiar with and to offer helpful suggestions about.

Certain symptoms naturally indicate a possible pelvic complaint. Some of these should be considered serially, so that their significance and management may be fully appreciated. Generally, menstrual disturbances, pelvic pain and discomfort or annoying vaginal discharge, either alone or in combination, are mentioned primarily, too often, however, the patient soon wanders far afield, pouring out a multiplicity of complaints that may well be referable to any system in the body and are sometimes sufficient to make the diagnosis of psychoneurosis a welcome escape for the harassed listener.

MENSTRUAL DISTURBANCES AND ABNORMAL BLEEDING

These disturbances may be in the form of amenorrhea, menorrhagia or metrorrhagia. Embarrassing indeed is the failure to consider pregnancy first when amenorrhea is complained of. I have not infrequently seen unmarried women of varying age, as well as married ones, well advanced in pregnancy in spite of a regime of estrogenic therapy. The physician should therefore inquire prudently and look well before regarding amenorrhea as a functional problem. If it apparently is one, he should not be hasty with estrogenic and allied injections, especially in the young patient not far removed

*Presented at the New England Postgraduate Assembly, Boston, October 30, 1946.

†Professor of obstetrics and gynecology, head of Department and director, Division of Gynecology, Jefferson Medical College and Hospital.

from the onset of puberty — such treatment may do more harm than good by physiologic interference with a delicately balanced pituitary-ovarian mechanism. The general physical condition may be at fault, and medication along the lines of vitamin and ferruginous therapy may well complement wholesome reassurance and advice about diet, activity and personal hygiene. In the presence of obesity, especially of relatively recent onset, desiccated thyroid is still the most dependable endocrine product, but careful observation of tolerance to the drug is imperative. It is not always essential to estimate the basal metabolic rate before the empirical effect is noted, unless easy means for its determination is at hand. Nor is it necessary to have hormonal assays immediately in functionally amenorrheic patients. Patients falling into this category need not be referred to the gynecologist or endocrinologist until a reasonable time has elapsed with employment of the measures mentioned. When there is marked or progressive alteration in secondary sex characteristics, however, it is best to seek specialized advice, for the rare possibility of a masculinizing tumor of the ovary or a similar neoplasm of the pituitary or adrenal gland must be borne in mind.

It is well to remember that amenorrhea is only one symptom of the menopause. I cannot caution too strongly against the indiscriminate way in which estrogenic therapy is prescribed for any and all symptoms that patients may exhibit or let themselves think they must develop, when regular menstruation ceases sometimes after forty or forty-five years of age. A legend has grown up that vasomotor and nervous symptoms must develop at this time. Many a woman without such symptoms may anxiously seek endocrine therapy or even have it suggested for her, not only by friends but also by physicians themselves. Frequently, explanations and reassurance, with and without mild sedation, suffice in the management of these unpleasant vasomotor symptoms. I am inclined to believe that estrogenic therapy, employed regularly and over a long period, actually prolongs menopausal phenomena in certain cases, and we are all more or less familiar with the confusing picture produced during the postmenopausal period when so-called "withdrawal bleeding" occurs in the course of prolonged hormonal medication.

Bleeding, either menorrhagia or metrorrhagia, or both, causes most physicians a good deal of concern both in diagnosis and in management. The first point is to determine the source of the bleeding, and the next to decide whether it is organic or functional. This is sometimes difficult to do exactly, for the possibilities may overlap, owing to existing lesions combined with functional disturbance. For this reason, a careful history is essential, and the patient's decade of life is of extreme importance be-

cause of the relative frequency of causative factors likely to appear in certain age groups.

In abnormal bleeding from the genital tract in the child or the young girl approaching puberty, local causes of an organic nature, either benign or malignant, are rare, whereas constitutional or endocrine disturbances, or both, are much likelier to be at fault. Such disturbances cannot be assumed, however, until a careful pelvic examination is made in addition to a general physical survey. If a hemoglobin estimation is particularly low, a complete blood count, with bleeding and clotting times, should be taken, not only to determine any degree of anemia but also to exclude a blood dyscrasia. Tuberculosis or heart disease may be a factor, or dietetic inadequacy may be associated with metabolic disturbance and vitamin deficiency. One should not hesitate to make a pelvic survey, having excluded the general factors mentioned, before deciding on an endocrine imbalance. This can be accomplished under suitable conditions with understanding and gentleness. External viewing of the genitalia and rectal examination may be supplemented by direct inspection of the vagina through a Kelly cystoscope with reflected light or by the use of an electrically lighted instrument. Thus, a foreign body can readily be eliminated, and any peculiar lesion that might indicate a neoplasm can usually be seen if present. Bimanual rectal examination may reveal an ovarian tumor. If so, a rare feminizing tumor may be involved, although the absence of an ovarian enlargement may merely mean precocity, as Novak³ has carefully pointed out. In any event, the finding of an organic pelvic lesion means that the young patient should then be referred to the specialist.

An endocrinopathy is probably the most frequent and probable cause of these disturbances. Immediate recourse to hormonal injections should be avoided. Often, these endocrine disturbances, like amenorrhea, are self-limited and respond to reassurance and general measures. Thyroid may be tried to advantage, and if it is not satisfactory, estrogen and progesterone therapy may be instituted. Testosterone may be effective as a stop-gap in the control of abnormal bleeding, but the dosage must be guarded, since the masculinizing effects of testosterone are well known. Gonadotropic hormones have been largely discarded by thoughtful endocrinologists. All in all, hormonal therapy should not be used indefinitely, for it cannot be determined with certainty what future maladjustment may result from the interference with the natural delicate endocrine balance. I have seen little good result from snake venom or styptics. If no improvement results after a reasonable trial of carefully managed endocrine therapy, the problem should be put up to the specialist, with curettage, hormonal assays and complete metabolic studies. Curettage is sometimes not only diagnostic — to

prove hyperplasia of the endometrium — but also curative for a long time, and repetition may be necessary. Even blood transfusion may have to be resorted to. Most physicians avoid irradiation in these young patients, and major pelvic surgery for functional disturbance of this nature is rarely if ever necessary. It is a wise practitioner who recognizes relatively early when he is getting nowhere with office therapy.

During the reproductive period, one is much likelier to find organic than functional causes for abnormal bleeding. First to be thought of are the abnormalities associated with pregnancy — threatened or incomplete abortion, premature separation of the placenta, or placenta previa, and ectopic pregnancy. The general practitioner doing obstetrics knows from his own experience when to seek help and is limited only by his ability to obtain such help in any of the conditions mentioned. The patient who continues to bleed from an incomplete abortion and, naturally, one suspected of harboring an ectopic gestation require reference to the specialist. In such a case it is clear thinking to consider every threatened or incomplete abortion as a possible extrauterine pregnancy.

Unhealed lacerations with eversion, erosion, polyps and subinvolution may be responsible for abnormal bleeding, and office treatment may be of great benefit. Local applications to the cervix and the use of tampons, carried out indefinitely, require time and are of no permanent value, except perhaps to the income of the practitioner. Well considered cauterization, on the other hand, is beneficial. Subinvolution, if accompanied with retrodisplacement, is often benefited by prolonged hot saline douches, the use of the knee-chest position and the judicious use of the pessary, with appropriate care in its employment. Polyps, if superficial, may be excised, and the base cauterized. The removed polyp should always be sent to a pathologist for study. I believe that the mere finding of a polyp calls for diagnostic curettage to exclude others in the uterine cavity or endometrial disease of another nature that may be a more probable cause of the bleeding, this should be a hospital procedure.

During this period one may also discover fibromyomas of the uterus and true ovarian tumors. The necessity of distinguishing between the malignant tumors and the non-neoplastic or so-called "retention cysts" of the ovary is discussed below. Naturally, lesions of the nature mentioned, if found or suspected, should be referred to the specialist for decision. The predominant thought, however, when abnormal bleeding is complained of in the reproductive period, should be of the possible existence of cervical carcinoma, and the need for early diagnosis and prompt treatment is obvious. Although the Papanicolaou vaginal-smear test may be indicative of cancer, a thorough cervical biopsy and an adequate study of the tissue by a com-

petent pathologist must be relied on to give the final answer.

Abnormal bleeding in the menopausal and postmenopausal patient may be caused by senile vaginitis, and the use of an astringent douche primarily, followed by a lactic acid douche to maintain the normal acidity of the vagina, may be all that is necessary. Estrogenic suppositories may help, but I am averse to prolonged estrogenic therapy, either by mouth or by injection, because the factor of "withdrawal bleeding" may have to be reckoned with sooner or later. Decubitus ulceration is sometimes seen in the prolapsed uterus and also occurs with irritation due to a neglected pessary. Local treatment only helps to prepare the patient for the surgical procedure that may be necessary to cure the prolapse. Nonimprovement demands biopsy, if one is to be on the safe side.

The danger signals that menopausal and postmenopausal bleeding present should be re-emphasized. The physician should not procrastinate, when such bleeding is present, even though no pelvic abnormality can be seen or felt. No local or general treatment is indicated for bleeding from the inside of the uterus. Only curettage in the hands of one qualified to carry the problem through to its final conclusion is the answer to this problem, and here again it is the pathologist who must give the final answer after careful study of the tissue. Hormonal therapy for the treatment of this symptom is not only injudicious but actually dangerous. Macfarlane³ recently reported 18 cases of postmenopausal bleeding due to estrogenic therapy, with an unnecessary hysterectomy resulting in one. The physician should pass the responsibility to the gynecologist.

PELVIC PAIN AND DISCOMFORT

Pelvic pain and discomfort are generally associated with pelvic lesions, which may also cause referred symptoms that bring the patient to the doctor. An important thing to remember is that the presence of a pelvic abnormality, per se, does not necessarily explain the symptomatology, nor does a pelvic lesion invariably cause pain. An example is afforded by the problem of retrodisplacements of the uterus. How often is this malposition blamed as the cause of backache, and treatment instituted or operation advised, when the true cause may be found in an orthopedic or other extrapelvic lesion. Acquired retrodisplacements may cause backache but manual replacement and the use of a properly chosen pessary constitute a therapeutic test that should never be neglected before surgery is advised. Too often, surgery is recommended for congenital retrodisplacement. I do not believe that this condition is ever the sole cause of pain or discomfort unless it is complicated by pelvic inflammatory disease or endometriosis.

Renal lesions may simulate a variety of tubo-ovarian disease or appendicitis as well. The necessity of evaluating urinary findings only if the specimen obtained is a catheterized one is emphasized. Reported pus or blood in the urine may well come from a contaminating vaginal discharge should a voided specimen be relied on.

It is unfortunate that uterine carcinoma seldom causes pain until the lesion is well advanced. Vulval or primary vaginal cancer may cause pain, however, when the lesion is beginning and small in extent. Therefore, to exclude cancer, any genital sore that does not heal readily should be viewed with suspicion and biopsied promptly, as well as being studied for a venereal cause. Perhaps it is better to refer such cases promptly to a specialist.

Fibromyomas frequently cause pain and distress, and when such symptoms are investigated pelvicly, either with or without bleeding symptoms, reference to the specialist for appropriate treatment is desirable. Symptomless myomas, on the other hand, may be observed at regular intervals to note their progress or regression, but the patient should always be told of their presence. This is a double protection.

Pelvic inflammatory disease of gonorrheal, postpartum or postabortal origin is usually easy to recognize, for pain is the predominant symptom. Today's treatment, with chemotherapy and particularly with penicillin, is a valuable adjunct to the conservative management that has been in vogue for so long. After subsidence of the acute symptomatology, prolonged hot saline douches and diathermy do much to help Nature in restoring the pelvic organs to normal. Rarely is surgery necessary, except in the presence of a pelvic abscess, when drainage of the cul-de-sac is indicated or when repeated attacks have occurred from time to time. Tuberculous pelvic inflammatory disease is suspected when fever and symptoms do not subside in a reasonably short time, particularly when there is an antecedent history of tuberculosis or suggestive chest findings. Pelvic endometriosis may simulate pelvic inflammatory disease, but the etiology of the latter is lacking in the history. Endometriosis presents a difficult problem in treatment. Testosterone treatment may perhaps be beneficial, if the diagnosis is an accurate one. This is not always possible, however, it must often be a presumptive diagnosis, and it is better to let the specialist decide whether or not surgery is the answer.

Ovarian enlargements are a frequent cause of pelvic pain. The responsibility of advising surgery in these cases is grave, for the primary decision is a differentiation of non-neoplastic cysts, better known as retention cysts or graafian follicle and corpus luteum cysts, and true ovarian neoplasms. Repeated examinations will help to determine this, for neoplastic growths of the ovary continue to enlarge, whereas retention cysts, being functional, tend

to alter or regress. Far too many ovaries are sacrificed by injudicious advice and by even more injudicious surgery. On the other hand, a progressively enlarging tumor demands reference to the specialist, because it may represent any variety of ovarian neoplasm, either benign or malignant. Sizeable tumors, when primarily found or when torsion of the pedicle is suspected, need prompt surgical treatment.

Finally, dysmenorrhea may be an accompanying symptom of any of the organic pelvic lesions mentioned above, but the most frequent, perhaps, is the type known as essential dysmenorrhea, which is present without demonstrable organic change, unless an acutely anteverted uterus is regarded as an organic abnormality. Although such anteversion may play a part mechanically, it is more probable that constitutional or endocrine influences, or both, and neuropsychiatric factors are to blame. I have nothing new to offer in the office control of these patients. Broad principles of management must be relied on. Reassurance and the prolonged psychosomatic approach are often necessary in addition to the correction of physical, hygienic, nutritional and environmental obstacles. Every hormonal and other remedy in the books has been tried, with testimony for and against each, by equally enthusiastic and reputable investigators — so that one can "pay your money and take your choice." Accompanying symptoms — headache, gastrointestinal disturbances and vasomotor and nervous symptoms — add to the difficulty of specific medication. Pregnancy usually relieves the trouble, but unfortunately the problem of sterility enters into the picture in some of these married patients. Antispasmodic remedies reinforced with barbiturates and codeine help the majority, the most obstinate cases should have a dilatation and curettage, or even a stem pessary. Sympathectomy is losing its popularity. I strongly believe that in the most stubborn cases, an organic lesion, particularly endometriosis, has been overlooked primarily and must be corrected.

ABNORMAL VAGINAL DISCHARGE

A certain amount of vaginal secretion is normal and readily explained on a physiologic basis — that is, normal glandular activity in the Bartholinian and cervical glands, with a reaction in the neighborhood of pH 5 or less. It is supposed that the correlation of enzymatic activity and the presence of a normal flora in the vagina, governed by the bacillus of Döderlein, maintains normalcy. This delicate balance is readily destroyed by bacteriologic infection of varying degree.

Abnormal vaginal discharge can result from a multiplicity of causes. The most frequent is eversion of the cervical mucosa due to lacerations and accompanied by hypersecretion and low-grade infection, which may result in erosion and may be accompanied by hypertrophy and cystic degenera-

tion — the entire process being covered by the overall diagnosis of cervicitis or endocervicitis. Occasionally, one sees congenital eversion or erosion, or both, in the virgin, the result of a developmental error — based on failure of the hypertrophied cervical mucosa, stimulated in utero by the mother's estrogens, to regress at birth.

Next in frequency is the discharge due to gonococcal infection, which involves Skene's tubules, Bartholin's glands and most frequently and persistently the glands of the cervical canal. Secondary irritation of the vagina and vulva then follows, and a profuse and offensive discharge results.

Often seen and readily recognized in a wet smear is a *Trichomonas vaginalis* infection, which is often due to the prolonged activity of this flagellate in an unhealthful environment, as noted above. The primary source of this organism is still a moot question, but its presence is associated with a most annoying and irritating discharge. Yeast fungi, principally of the *Monilia* group, act in a similar fashion.

Discharges, of varying degrees and amount, of course, accompany serious lesions, principally carcinoma of the external genitalia and uterus due to secondary infection of necrotic tissue. Pyometra, caused by cervical-canal stenosis, cancer or degenerating myomas, also falls into this group. Pruritus based on metabolic disorders, such as diabetes, and giving rise to local irritation and itching may also be accompanied by discharge. The breakdown of venereal and granulomatous lesions or of tuberculous ones has a similar effect.

The principal responsibility of the general practitioner is to try to recognize the cause. In the group mentioned above it is obvious that reference to the specialist is desirable in most cases, especially when a possible neoplasm exists.

In the treatment of a discharge associated with acquired eversion of the cervical canal, douches and local applications require time and are usually inadequate. The nasal-tip cautery, however, may be employed as an office procedure, provided there is no acute infection as evidenced by a history of possible gonorrheal infection, the presence of fever and the existence of pelvic inflammatory disease, as determined by bimanual examination. In cases in which marked hypertrophy and extensive cystic degeneration are present, however, endothermic resection or a plastic operation — both of which are essentially hospital procedures — had better be employed.

Of especial benefit is the light cauterization of the congenital type of eversion, which can be accomplished in the virginal girl by exposure of the cervix with a small speculum or Kelly cystoscope but is frequently impossible because of the young patient's natural sensitivity, and it is necessary to carry out the treatment under anesthesia as a hospital task. In all cases of cervical cauterization subsequent

dilatation of the cervical canal is desirable at indicated intervals to lessen the incidence of atresia or stenosis, a sterile uterine dressing forceps can be used effectively. Lactic acid douches may be advised after complete healing has taken place.

When *T vaginalis* infections are discovered, it is perhaps better to clear up any abnormalities that exist to ensure less likelihood of recurrence, although it is quite permissible to attack the infestation primarily to promote symptomatic relief. The remedies employed are legion, the important thing to remember is to attempt to restore the normal flora of the vagina as quickly as possible. I prefer the use of silver picrate, by insufflation and suppository, first to destroy the trichomonads, the reaction being maintained thereafter by the regular use of lactic acid douches (a teaspoonful to 2 quarts of warm water). In persistent cases infection of the urinary tract and a partner harboring the organism in the prostate gland should be sought. *Monilia* infestations are handled in almost similar fashion, with a keen lookout for an excess of sugar in the blood or urine, or both.

Discharge due to gonorrheal infection may be due to the initial attack, to recurrence or to chronic infection of Skene's tubules, Bartholin's glands or the cervical glands. Smears and cultures are helpful, but may not give positive results. In any event, if the history and clinical findings are sufficient to warrant a presumptive diagnosis, local measures should be avoided in the acute and subacute stages, chemotherapy and penicillin being depended on. Later, chronic infection may be eradicated with the cautery or endotherm, Skene's tubules and the Bartholinian glands being also regarded as foci. If gonorrheal infection has ascended beyond the cervix, as indicated by evidence of pelvic inflammatory disease on bimanual examination, one should by all means go slowly in prescribing local treatment. In such cases chemotherapy and penicillin are of little help, and the physician must wait for further subsidence of the inflammatory process before resorting to anything else. Later, cleansing douches, particularly prolonged hot saline douches, will be found most helpful in restoring the pelvis to normal or in alleviating pain and menstrual disturbance. The question of subsequent surgery, because of organic or functional disability or because of repeated attacks, is for the specialist to decide.

INFERTILITY

Finally, regarding the problem of the barren marriage, I must speak cautiously, for I am within the very citadel of research and wisdom that pertains to infertility. Fortunate is the practitioner of New England, who can send his problems to Boston!

The couple who seek advice should be persuaded that any studies must be on a partnership basis. The husband must be excluded as the partner at fault, if possible, is lessened. Only if no

organic disease can be detected in the woman's pelvis is a tubal insufflation test indicated, the examiner should beware of telling the woman that she has a "tipped womb" and can never conceive, for his face may be red nine or ten months later. Proceptive advice, especially concerning the ovulatory period, may be given and practiced even before tubal insufflation. The physician should depend on desiccated thyroid before resorting to a galaxy of hormonal injections, and should not

overlook constitutional defects in either partner. If after a reasonable trial of sane advice and simple measures along these lines, he believes that he has failed, he should seek counsel of the specialist — who may do no better.

Q FEVER*

Report of a Case

MAXWELL FINLAND, M.D.,† AND MARK F. LESSES, M.D.‡

BOSTON

THE speed of modern travel and the relatively long incubation period of many infectious diseases have made it necessary for the physician to have some acquaintance with global epidemiology, to cope with some of his diagnostic problems. In the case reported below a diagnosis of Q fever was established serologically in a patient with clinical findings of primary atypical pneumonia. The diagnosis was suspected from the fact that the patient had been in an area where the causative agent of the disease occurs and had returned from that area within the known incubation period of the disease.

I. M., a 56-year-old merchant, became ill on March 3, 1947 while on a transatlantic steamer returning to the United States from a 3 month business trip in Europe. The illness began suddenly with chills, generalized aching, anorexia, malaise, dizziness and slight diarrhea. There was also a slight cough without pain. The patient was seen on the same day by the ship's physician who found the temperature to be 103.8°F., the pulse 116, and the respirations 36. Examination revealed no abnormal findings except "slight respiratory roughness on auscultation." Urinalysis then showed a slight amount of albumin. The temperature on the following day dropped to 99.8 F., but on March 5 was again found to be 103.4 with a pulse of 110 and a respiratory rate of 40. Meanwhile the patient continued to cough and he raised small amounts of blood flecked sputum. He was given fluids liberally some pills (probably aspirin) and two injections of penicillin in-oil during these 2 days without benefit. He felt comfortable except that he perspired profusely especially after taking the pills. The ship docked in New York on March 5, and the patient came directly to Boston by plane and was admitted to the Beth Israel Hospital on the following day. He had no pleural pain or headache and had not noted any blood in the stools.

*From the Medical Service, Beth Israel Hospital; the Thorndike Memorial Laboratory and Second and Fourth Medical Services (Harvard) Boston City Hospital, and the Department of Medicine Harvard Medical School.

†Associate professor of medicine Harvard Medical School; chief, Fourth Medical Service, and associate physician Thorndike Memorial Laboratory Boston City Hospital.

‡Instructor in medicine Harvard Medical School; associate visiting physician and clinical pathologist, Beth Israel Hospital.

We are indebted to Dr. J. B. Maguire, medical officer of the Quarantine, for an abstract of his record of this case.

The patient had had diphtheria at the age of 10 but gave no other history of infectious diseases. He was known to have had slight hypertension for a number of years. He had also had frequent colds but none that were severe. For the past several years he had noted occasional substernal pressure on exertion that was relieved by belching.

Physical examination revealed a well developed and somewhat obese patient. He was well oriented but appeared acutely ill and feverish, perspiring profusely, breathing rapidly, coughing frequently and raising small amounts of tenacious blood streaked and rusty sputum. Examination of the chest revealed limited expansion of the right side. Over the lower half of the right portion of the chest posteriorly there was moderate dullness with numerous rales crepitant rales at the end of inspiration and after coughing some coarse rhonchi on expiration and diminished tactile fremitus, spoken voice and breath sounds. The left lung was normal. There were no skin lesions, the spleen was not felt, and the rest of the physical examination revealed no abnormalities.

The temperature was 104 F., the pulse 108, the respirations 38 and the blood pressure 138/86.

The patient was given 50,000 units of crystalline penicillin G in aqueous solution intramuscularly every 3 hours until March 13. He also received 8 cc. of elixir of terpin hydrate with codeine every 4 hours for 3 days after which the drug was discontinued because of nausea and epigastric distress. No other medication was given. The temperature chart is presented in Figure 1. The patient continued to sweat profusely until the temperature reached normal. The cough continued throughout the febrile period and then abated. The sputum was blood tinged until March 9 thereafter it was mucopurulent and scant and no sputum was raised after March 11. The patient appeared to be quite comfortable and cheerful throughout most of his hospital stay except for some restlessness at night during the height of the fever. His appetite remained poor during the febrile period but began to improve after March 9. Epigastric distress was present from the time of admission until March 11. After the temperature reached normal the patient began to improve rapidly although the physical signs in the lungs remained essentially unchanged until discharge from the hospital on March 19.

X-ray examination of the chest on March 6 revealed findings that were consistent with a segmental pneumonia in the anterior and lower portions of the right lower lobe with an associated atelectatic component. The configuration of the heart and aorta suggested hypertensive heart disease. On March 8 the consolidation of the right lower lung was somewhat smaller in extent. Films taken 3 days later showed a further decrease in the extent of consolidation at the right base and no new abnormalities. The roentgenograms and

fluoroscopic findings on March 17 also indicated a further decrease in the extent of the segmental consolidation in the right lower lobe. There was definite evidence of retraction of the interlobar fissure, suggesting a persistent atelectatic component in the pneumonic consolidation at that time. Re-examination on May 12 showed almost complete re-aeration of the right lower lobe, with only a small triangular area of consolidation adjacent to the anterior interlobar fissure. The lung fields were otherwise clear. Both leaves of the diaphragm were in normal position and showed normal excursion by fluoroscopy. The anteroposterior and lateral views of the chest on March 6 and on May 12 are presented in Figure 2.

Urinalysis on admission showed a ++ test for albumin and a rare white blood cell in the sediment but 2 days later was negative. Examination of the blood revealed a red-cell count of 4,610,000, with a hemoglobin of 13.0 gm per 100 cc, and a white-cell count of 11,500, with 72 per cent neutrophils, 22 per cent lymphocytes, 5 per cent monocytes and

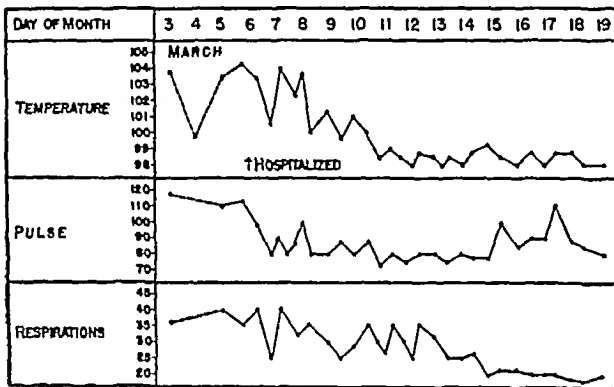

FIGURE 1 Clinical Chart

1 per cent eosinophils. On the following day the white-cell count was 11,600, with 84 per cent neutrophils, 10 per cent lymphocytes and 6 per cent monocytes. A few of the neutrophils showed toxic granules. The sputum showed gram-positive cocci in pairs and chains and no acid-fast bacilli in the stained smears, and cultures showed a predominance of alpha-hemolytic streptococci. Blood cultures taken on admission were negative. Cultures of the stools on March 9 and 10 yielded no pathogenic organisms. The serums on March 7 and 19 were negative for typhoid and paratyphoid agglutinins. Tests for cold agglutinins and for antibodies against influenza A and B viruses (Hirst test) on serums obtained on March 11 and 19 and April 30 were negative. An electrocardiogram taken on March 13 was suggestive of an old anterior myocardial infarct, but no changes of significance were noted in later electrocardiograms.

Complement-fixation tests for Q fever were carried out with the patient's serum by Dr. Herald R. Cox, of the Section of Viral and Rickettsial Research of the Lederle Laboratories. The strain used in these determinations was the original American strain isolated from *Dermacentor andersoni* at the Hamilton, Montana, laboratory of the United States Public Health Service and was originally called the "Nine-Mile Strain". The results were reported as follows: March 11, ++++ in a dilution of 1:16, March 19, ++++ in a dilution of 1:128, and April 30, ++++ in a dilution of 1:256 and ++ in a dilution of 1:512. These results indicate that the patient undoubtedly had Q fever.

The essential features of this case were the sudden onset with chilly sensations, anorexia, cough and mild diarrhea, the temperature of 102 to 104°F with a relatively slow pulse for six days, gradual defervescence between the sixth and ninth days, marked sweating throughout the febrile period,

increased at first by antipyretics, marked to moderate cough productive of small amounts of blood-streaked and rusty sputum throughout the febrile period, an increased respiratory rate without dyspnea, moderate to mild illness with only occasional periods of restlessness during the height of the fever, physical and roentgenographic evidence of atypical pneumonia and segmental atelectasis limited to the right lower lobe with residual x-ray findings in that area after more than two months, absence of pleural pain, rash or palpable spleen, slight neutrophilic leukocytosis, negative cultures for pathogenic organisms in the blood, sputum and stools, negative serologic findings for enteric agglutinins, cold agglutinins and for the viruses of influenza A and B, and, finally, a significant and progressive increase in the titer of complement-fixing antibodies for the rickettsia of Q fever after the middle of the second week of the disease, the titer remaining elevated after the eighth week.

Rickettsia burnetti,² the causative agent of Q fever, has been recovered under natural conditions, either in infected ticks or from human cases, in Australia,³ in several western states in this country from Texas to Washington,⁴ in Italy,⁶ in the Balkans⁶ and in Panama.⁷ An outbreak among troops in Camp Patrick Henry, Virginia, originated in Italy.⁸ In Australia, Q fever is essentially an occupational disease affecting chiefly slaughterhouse workers, dairy hands and foresters.⁹ The recent outbreak in Amarillo, Texas, involved stockyard and packing-house workers.⁹ Several outbreaks have been described among personnel in laboratories where work with the agent was carried out,¹⁰⁻¹⁴ and at times affected persons who had not had direct contact with the agent. Infection in most cases is presumed to be by inhalation of infected materials. There was a history of a tick bite in some American cases that occurred in areas where the rickettsia of Q fever has been found.⁴ The exact mode of transmission of the disease to human beings, however, is not known.

Pulmonary lesions have not been recognized as a prominent feature of Australian Q fever. The signs and x-ray findings of atypical pneumonia were first described in the outbreak at the National Institute of Health.¹⁰ They were an important feature of the first authenticated case that was naturally acquired in this country¹⁵ and in the various groups of cases studied by the Army units,^{7, 11, 12, 16, 17} as well as in the Amarillo outbreak.¹⁸

The findings shortly after admission in the case reported above were those of a primary atypical pneumonia. A brief survey of the itinerary of the patient indicated that he had been in Italy in the vicinity of Naples for two or three weeks before the onset of symptoms. The possibility of Q fever was therefore immediately suspected on the basis of the reports of the occurrence of that disease in

association with atypical pneumonia in this region and in other parts of Italy. Suspicion was further

stored in supply depots in that vicinity. Although he was not aware that any of the buildings that he

FIGURE 2. X-ray Films of the Chest on March 6 (above) and on May 12 (below)

increased when inquiry revealed that the patient had spent about ten days in the vicinity of Naples inspecting United States Army stocks that were

visited had been used for housing livestock, such a possibility could not be excluded. Most of the military cases reported from that area occurred

crucial value of spinal anesthesia — the status of the gastric contents is not of vital importance if spinal anesthesia is employed. It is also strongly believed, as mentioned above, that the risk is markedly increased as the dosage is increased and that the reported deaths under spinal anesthesia were a result of excessive dosage.

There were no permanent neurologic sequelae. This feared complication must be recognized as a potential hazard but should not be distorted out of all proportion. Shimberg⁹ investigated 14,073 patients receiving spinal anesthesia at a Veterans Administration hospital and reported 2 cases of nonspecific meningitis and 3 cases of peripheral neuritis. These were transient, with no permanent paralysis or loss of sensation. Stein and Tovell¹⁰ state that in a series of over 10,000 patients receiving spinal anesthesia at the Mayo Clinic no permanent motor paralysis has been encountered. The risk is present, but the incidence of this complication does not justify the exclusion of a valuable method of anesthesia.

There can be little doubt that any method of regional anesthesia has the least harmful effect on the fetus. Effects on fetal respirations are a result of one or more of the following factors:

Premedication The use of regional anesthesia has conclusively proved that sensible, conservative premedication with the barbiturates and scopolamine has no deleterious effect on the fetal respirations. Morphine sulfate has been employed in a small number of cases when deemed advisable, and even this dreaded obstetric narcotic has exerted little if any influence on the fetal respiration when spinal anesthesia was used.

Anesthetic drug The volatile liquid inhalation agents, such as ether, chloroform and vinethene, and the gases, such as cyclopropane, ethylene and nitrous oxide, are capable of exerting their effects on the fetus. Pentothal Sodium also enters the fetal circulation and can narcotize the fetus, but 50 mg of procaine deposited in the spinal canal has thus far demonstrated no effect on fetal respirations.

Hypoxia No inhalation agent permits the use of 100 per cent oxygen in the inspired mixture at all times. Nitrous oxide and oxygen is notoriously prone to produce hypoxia, and this is in fact necessary to a certain extent to produce anesthesia of the third plane. The other inhalation agents vary only in the extent of oxygen deprivation. This hypoxia is transmitted to the fetal brain. It is pertinent to make special mention of cyclopropane, whose proponents have always stressed the high concentration of oxygen that can be permitted with this drug. It is well to caution that the amount of oxygen flowing into a closed system does not indicate the blood saturation with oxygen. Cyclopropane, with its

lack of respiratory stimulatory effect, does not ensure against hypoxia even though the mixture contains 80 or 90 per cent oxygen. The drug can also enter the fetal circulation and depress the respiratory system with resulting fetal anesthesia, hypoxia and brain damage. Great care must be exercised if cyclopropane is used, so that this complication is not encountered.

Only with the employment of regional methods of anesthesia or in the absence of anesthesia can one be sure that the maternal respirations are affected to the least possible degree. In the event that they are altered 100 per cent oxygen can be administered for an indefinite period without affecting the anesthetic intensity or depth. The routine use of oxygen is advocated during the period of actual delivery.

A discussion of the general indications and contraindications of spinal anesthesia is not warranted here. The only obstetric contraindication is the decision to perform an internal podalic version, in which uterine relaxation is mandatory. Cleland's¹¹ neurologic study has shown that regional anesthesia limited to the spinal nerves below the tenth thoracic segment will not interfere with uterine tone or contractility. Therefore, it is not suitable in this obstetric maneuver, unless larger dosages of spinal anesthesia are employed. Deep ether is preferred. All other types of delivery can be performed under spinal anesthesia.

No discussion will be entered into regarding spinal anesthesia in cesarean section except to state that it was employed in all sections performed at the Army Air Forces Regional Hospital. The procedure carried no mortality or morbidity and was the method of choice.

The satisfactory and safe employment of spinal anesthesia is considered to depend chiefly on the following factors, which must be rigidly adhered to: the first and most important is the administration of a small amount of anesthetic drug, such as 50 mg of procaine; the second factor is the introduction of the drug at a low level — that is, the third or fourth lumbar interspace; finally, ephedrine sulfate must be administered just prior to the anesthesia.

It is our opinion that spinal anesthesia has the following advantages in obstetrics: completely painless delivery, complete control over progress of the delivery by the obstetrician, complete relaxation of the perineum, elimination of an inhalation anesthetic and thus a lower incidence of pulmonary complications, no distortion of the perineum by injection of local anesthetic agents, absence of fetal depression due to anesthesia, and suitability for use on patients on whom general anesthesia is contraindicated — that is, its wide range of application.

SUMMARY

A series of 595 patients delivered by the pelvic route under spinal anesthesia is presented. The

technic is outlined, and the results obtained are discussed

MEDICAL PROGRESS

CURRENT CONCEPTS OF JAUNDICE, WITH PARTICULAR REFERENCE TO HEPATITIS (Concluded)*

LAWRENCE E. YOUNG, M.D.†

ROCHESTER, NEW YORK

INFECTIOUS AND SERUM HEPATITIS‡

The etiology of infectious hepatitis, like that of yellow fever, long remained a mystery, owing to a lack of susceptible experimental animals. During the war years, however, it was demonstrated by studies on human volunteers that the agent responsible for outbreaks of acute hepatitis is filterable and that it is present in the blood and stools and perhaps occasionally in the urine and nasopharyngeal washings of infected persons.⁴⁷⁻⁵⁴ Since it now appears that transmission occurs for the most part by fecal contamination⁵⁵⁻⁵⁷ and since ordinary chlorination of water fails to inactivate the agent,⁵⁸ it is imperative that patients with infectious hepatitis be subjected to isolation precautions similar to those employed in typhoid fever and dysentery, and that the disease be made reportable to public-health authorities.^{59, 60} Whether or not transmission also occurs by nasopharyngeal secretions remains an unsettled question.

The term "homologous serum jaundice" arose when it was learned that persons receiving pooled human serum or plasma, even in doses as small as 0.01 cc., were subjected to considerable risk of developing hepatitis.^{52, 61-64} This was found to be true regardless of the form in which the serum or

plasma was given. Jaundice was observed after the administration of measles and mumps convalescent serum,⁶⁵⁻⁶⁹ yellow-fever vaccine containing human serum,^{70, 71} pappataci-fever vaccine⁷² and liquid and reconstituted dried serum and plasma⁷³⁻⁷⁵ and also after transfusions of whole blood.^{65, 71, 72, 74}

Freezing, drying and storing do not seem to alter the icterogenic properties of plasma and serum.⁶⁴ It is possible that the process of fractionation of plasma also fails to inactivate the hardy agent of hepatitis. In fact, absence of jaundice in the thousands of persons injected with gamma globulin prepared from large pools of adult plasma can perhaps best be explained by the presence of specific antibodies in this fraction.⁶⁴ The prevention and attenuation of infectious hepatitis has actually been accomplished by administration of gamma globulin in controlled studies,⁶⁶⁻⁷⁵ but attempts to prevent homologous serum jaundice by this method have thus far yielded equivocal results. There have been no reports of hepatitis attributable to administration of normal serum albumin, another product of large-scale fractionation,⁷⁶ but the lack of such reports may be due to difficulties in conducting follow-up studies.⁶⁴

Since the icterogenic agent may be present in high titer in the blood of infected persons, and since only a small portion of donors are infective, the hazard of jaundice may be increased as the number of donors contributing to the pool is increased, provided specific antibody from some contributors to the pool is not present in amounts sufficient to neutralize the agent.^{64, 66} If a single donor is infected, the serum or plasma that he contributes may contaminate the entire pool. Although the period

*Presented in part at the annual meeting of the Vermont State Medical Society, Burlington, Vermont, October 4, 1946, and at a joint meeting of the Council of Rochester Regional Hospitals and the staff of the Veterans Administration Hospital, Bath, New York, November 14, 1946. In the preparation of this material no attempt has been made to include a complete review of the many controversial aspects of normal and abnormal bile-pigment metabolism. The aim has been merely to present, with illustrations, concepts that seem currently to be most acceptable and most contributory to an understanding of the pathogenesis of jaundice.

†Hearsey C. Buswell Fellow in Medicine, University of Rochester School of Medicine and Dentistry.

‡More complete reviews of the literature on infectious hepatitis and serum hepatitis have recently been presented by Hardy and Feinstone⁶⁰ and by Jelic.⁶⁴

§In a paper that appeared after the preparation of this study, Spangberg, Shown and Vaughan⁷⁷ reported an incidence of 7.3 per cent in 2049 patients receiving transfusions of pooled human serum or plasma. Definite jaundice did not develop within a five-month period of observation in any of 1284 patients given whole blood or in any of 1284 control patients who received no transfusions.

§Jancway⁷⁸ states that during the processing of albumin it is now possible to treat it with heat for two hours at 60°C., thus inactivating the thermal death time of a well studied strain of serum hepatitis virus. The practicality of this has been taken even though there have been no known cases of jaundice that could reasonably be attributed to the injection of any of the products of plasma fractionation.

of infectivity of hepatitis has not been conclusively established,⁹⁰ it is now realized that in the selection of donors for the preparation of serum or plasma or for any type of transfusion, care must be taken to exclude those who have had jaundice, exposure to infectious hepatitis or transfusions or injections of blood, plasma or serum within the preceding year.^{64, 84, 91} Donors who constitute the greatest threat are those in the preicteric stage of hepatitis and those who have hepatitis without jaundice.

The exact relation between homologous serum hepatitis and naturally occurring infectious hepatitis

TABLE 1 *Comparison of Infectious Hepatitis and Serum Hepatitis*

CHARACTERISTICS	INFECTIOUS HEPATITIS	SERUM HEPATITIS
Etiologic agent		
Filterable	Yes	Yes
Resistant to heating, freezing and drying	Yes	Yes
Pathogenic for man only	Yes	Yes
Disease transmitted by administration* of		
Serum (P, O, N)	Yes	Yes
Stool (P, O, N, G)	Yes	No
Duodenal washings (O)	Yes ⁹²	No reports
Urine (O, N)	Irregular ⁹² "	No reports
Nasopharyngeal washings (N)	Irregular ⁹² "	Irregular ⁹² "
Disease spread by personal contact or by fecal contamination of food and water	Readily	Rarely ⁹²
Incubation period	14-35 days†	40-160 days†
Pathology	Same as that of serum hepatitis	Same as that of infectious hepatitis
Clinical features	Similar to those of serum hepatitis	Similar to those of infectious hepatitis
Attack confers immunity to infectious hepatitis‡	Yes ⁹⁴	No ⁹² "
Attack confers immunity to serum hepatitis	No ^{94, 95}	Yes ⁹⁴

*The routes of administration are indicated as follows: P = parenteral, O = oral, N = intranasal (and in certain cases, intrapharyngeal), and G = gastric.

†Reported incubation periods in a few cases fall outside the ranges given. Neefe et al.⁹² have shown that the period between inoculation of icterogenic serum or plasma and the first manifestations of hepatitis may be as short as twelve to thirty-five days, although clinical jaundice may not appear until much later.

‡A possible example of heterologous immunity is cited by Oliphant,⁹³ who produced typical homologous serum jaundice in 4 of 11 volunteers inoculated with serum from a patient with naturally occurring infectious hepatitis, no jaundice developed in 10 inoculated control subjects who had previously had homologous serum jaundice.

is not yet settled.⁹² From the comparison presented in Table 1, it is apparent that there are at least two types of hepatitis virus that are immunologically distinct and that their incubation periods differ sharply. It is also significant that stools from patients with serum hepatitis have thus far proved noninfective when administered to human volunteers. Stools from patients with naturally occurring infectious hepatitis, on the other hand, have proved infective in a high percentage of trials. Despite these important differences, it seems likely that infectious hepatitis and serum hepatitis are caused by filterable viruses that are closely related and that the agent of serum hepatitis has been modified

through passage from person to person by artificial means.

Neefe, Gellis and Stokes⁹⁴ emphasize the fact that both the virus of serum hepatitis and that of infectious hepatitis can be transmitted by blood, plasma and serum. If the term "homologous serum hepatitis" is applied to all cases developing after the injection of blood products, the two types of viruses must be kept in mind. It must also be appreciated that both viruses can probably be transmitted by the use of unsterilized syringes and needles in the drawing of blood or the injection of any type of substance.⁹⁹⁻¹⁰² Transmission is particularly apt to occur in this way when diagnostic, therapeutic or prophylactic procedures are carried out on large groups of people, as in diabetic¹⁰³ and syphilitic clinics.^{94, 99, 104-109} It seems likely, in fact, that a considerable number of patients who develop hepatitis during the course of antisiphilic therapy are actually suffering from syringe-transmitted virus hepatitis rather than from the toxic effects of arsenical drugs on the liver. The extent to which arsenic modifies the response of the liver to viral invasion is unknown.¹¹⁰

Recent observations by Lucké¹¹¹ and others¹¹²⁻¹¹⁴ confirmed Eppinger's¹¹⁵ earlier reports that so-called "catarrhal jaundice" is in most cases primarily a hepatitis, the principal lesions in fatal cases being those of acute yellow atrophy. The reported pathological findings in infectious hepatitis are essentially the same as those observed in serum and arsenotherapy hepatitis. Lucké^{111, 116} emphasizes the facts that less than 0.5 per cent of cases of epidemic hepatitis terminate fatally and that most patients make a complete and apparently permanent recovery.* There remain, nevertheless, a certain number of patients who survive the initial attack but continue for months or years to have clinical evidence of liver injury. The exact nature of the pathologic processes that take place and the relation between acute hepatitis and cirrhosis are not entirely clear.^{28, 29, 34, 118-120}

Bloomfield²⁸ suggests that the clinical course of hepatitis may be analogous to that of glomerulonephritis so far as latency and chronicity are concerned. Lichtman¹²¹ states, moreover, that in various studies of cirrhosis it is estimated that in 6 to 32 per cent of patients the cirrhotic process may have been initiated by an attack of acute hepatitis. The difficulties in making such estimates are obvious, however, in view of the facts that hepatitis may occur without jaundice^{23, 122, 123} and that many cases of hepatitis without clinical icterus have, no doubt, been incorrectly diagnosed as influenza or gastroenteritis. Diagnostic difficulties and other factors, particularly diet, must be taken into account in any evaluation of the relation between acute hepatitis and cirrhosis. It is hoped

*Although the mortality in epidemic hepatitis is uniformly low, that in homologous serum hepatitis is variable. A high mortality from serum hepatitis has been reported, particularly among wounded men.¹¹⁷

that more information on the incidence and pathogenesis of latent, recurrent and chronic hepatitis or cirrhosis will be forthcoming during the next decade as a result of follow-up studies on patients who contracted hepatitis, either naturally or by experimental inoculation, during World War II

LABORATORY TESTS FOR BILIRUBIN AND UROBILINOGEN

The several laboratory tests for hemoglobin derivatives that are most useful in the differential diagnosis of jaundice are worthy of brief comment.

The icteric index, which is determined simply by the matching of serum with standard solutions of potassium bichromate, provides a rough estimate of the degree of bilirubinemia. It does not, however, distinguish between bilirubinglobin and free bilirubin or between bilirubin and the yellow color due to hychromes, carotene and other substances, which are differentiated by the quantitative van den Bergh determination. The qualitative van den Bergh test has inherent faults, but the adaptation of this reaction by Malloy and Evelyn¹²⁴ for the measurement of serum bilirubin with the photoelectric colorimeter has proved to be of distinct value. According to Ducci and Watson,¹²⁵ the color that develops within a minute after serum and diazo reagent are mixed—that is, the direct one-minute value—is a quantitative expression of the qualitative prompt direct van den Bergh reaction, presumably owing to the presence in the serum of free bilirubin or sodium bilirubinate. The color that develops within fifteen minutes after serum is mixed with diazo reagent in addition to 50 per cent methyl alcohol is a measure of the total bilirubin—that is, bilirubinglobin and free bilirubin. The difference between the two values probably measures the amount of bilirubinglobin—the so-called “indirect type” of bilirubin—present in the serum. In retention jaundice the direct reading comprises a relatively small fraction of the total bilirubin present, and in obstructive jaundice, the reverse is true, and in the presence of hepatocellular necrosis, variable proportions may be found. Actually, the proportions of the two types of bilirubin present in the serum may fluctuate widely during the course of a single illness. This is particularly true in hepatitis, owing to varying degrees of cellular damage, intrahepatic biliary obstruction and cholangiolitis.

The upper limits for the direct fraction and for total serum bilirubin in subjectively healthy persons are approximately 0.2 mg and 1.0 mg per 100 cc.,* respectively.¹²⁷⁻¹²⁹ The ratio of icteric index to total serum bilirubin concentration in milligrams per 100 cc. cannot be stated accurately, especially for the normal and lower pathologic ranges. Accord-

ing to data available in the literature, the ratio may vary from 5:1 to 10:1, depending on the degree of hyperbilirubinemia, the chemical methods of measurement and, possibly, the proportions of the two types of bilirubin present.¹²⁷⁻¹²⁹ Serum with an icteric index of 100, for example, might be expected to have a total serum bilirubin concentration of from 10 to 20 mg per 100 cc. In the laboratories of the Strong Memorial Hospital the ratio has varied from 5:1 to 8:1 in the higher pathologic range and from 7:1 to 13:1 in the normal and lower pathologic ranges.

Examination of the stool is of the utmost importance in following the course of patients with jaundice. The pale or clay-colored stool, which is found in the presence of regurgitation jaundice, contains excessive amounts of fat and little or no urobilinogen. Diminution in the flow of bile impairs fat digestion and absorption, and since only small amounts of sodium bilirubinate are excreted into the duodenum, the amounts of urobilinogen found in the feces are correspondingly low. Gross inspection of the stool is essential but sometimes misleading because excessive fat may mask the presence of significant amounts of urobilinogen or urobilin.¹³ On the other hand, food pigments may give a brown color to stools containing little or no urobilinogen or urobilin.¹³¹ Watson and his associates¹³² have recently developed a simplified method for determination of the per-diem excretion of urobilinogen in the feces. It is admittedly crude, compared with more elaborate methods involving extraction with petroleum ether,¹³³ but it is sufficiently accurate to indicate trends in pigment excretion and sufficiently simple to be carried out quickly by inexperienced personnel. Fecal bilirubin is seldom measured in clinical studies because it escapes reduction to urobilinogen only in the presence of diarrhea and in newborn infants, in whom intestinal bacteria are not yet established.¹³

The simplified method for the determination of urobilinogen is also applicable to the urine.¹³²⁻¹³⁴ Serial tests of twenty-four-hour specimens or of samples collected between 2:00 and 4:00 p.m. are most useful and can be carried out in a few minutes. The significance of variations in urinary urobilinogen excretion is pointed out below. The foam test for bilirubinuria requires no reagents or equipment but is less sensitive and less specific than Harrison's test.¹³⁵⁻¹³⁶ Watson and Hawkinson¹³⁷ have recently described a semiquantitative modification of Harrison's test that appears to have merit. Strips of thick retentive filter paper impregnated with barium chloride are dipped in urine and then dried, and a mixture of trichloroacetic acid and ferric chloride is applied to oxidize the bilirubin to biliverdin. The depth of the resulting green color is compared with standards to give the approximate concentration in milligrams per 100 cc. This test has the additional advantage of convenience since the two materials

*Some of the higher figures for total serum bilirubin concentration are obtained by the method of Jendrassek and Grof¹²⁸ which Withers¹²⁹ attributes to that of Malloy and Evelyn.¹²⁴ Ducci and Watson¹²⁵ attribute the lower values obtained by Withers for the Malloy-Evelyn procedure to the use of alkali which was not recommended by Malloy and Evelyn.

required, the impregnated paper strips and the oxidizing agent, are easily prepared and usable for long periods¹³⁸ The Gmelin, iodine, methylene blue¹³⁸⁻¹⁴¹ and other tests^{135, 142} for bilirubinuria that have been described are less sensitive than Harrison's test and require no further comment

DIFFERENTIAL DIAGNOSIS

The illustrations presented below will serve to indicate how determinations of bilirubin in the

bilirubinuria are negative, but the amounts of urobilinogen found in the urine may be considerably increased if the liver is unable to re-excrete the large quantities absorbed from the colon In acute hemolytic processes, such as blackwater fever, red cells may be destroyed intravascularly, and the liberated hemoglobin may be excreted in the urine if the renal threshold is exceeded. If hemolysis is extensive, part of the hemoglobin may be broken down to hematin, which then unites with albumin

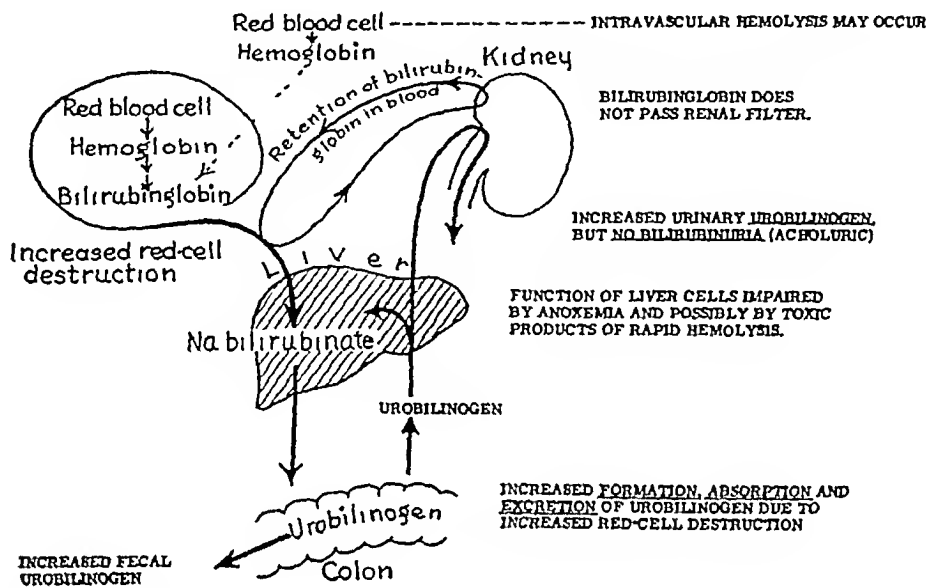

FIGURE 11 Abnormalities of Bile-Pigment Metabolism in Retention Jaundice Associated with Hemolytic Anemia

blood and urine and of urobilinogen in the urine and stool may be helpful in the differential diagnosis of jaundice

Figure 11 shows by means of heavy arrows that in hemolytic anemia increased red-cell destruction results in increased formation of bilirubinglobin, sodium bilirubinate and urobilinogen. The entire red-cell mass may, in fact, be turned over every few days^{143, 144}. Despite certain difficulties inherent in its measurement, increased excretion of urobilinogen in the feces is considered the most reliable index of rapid erythrocyte breakdown^{145, 146}. Urinary urobilinogen excretion is also increased as a rule during hemolytic processes, but the amounts found in the urine are subject to wide variation, depending on the extent to which urobilinogen is absorbed from the colon and metabolized by the liver. In patients with hemolytic anemia the function of the liver cells is impaired by anoxemia and probably by other factors, with the result that a portion of the excess bilirubinglobin delivered to the blood and carried to the liver from the reticuloendothelial system is retained in the blood. Since bilirubinglobin does not pass the renal filter, hemolytic jaundice is often referred to as acholuric jaundice. Tests for

to form methemalbumin, an apparently toxic substance. A large portion of the liberated hemoglobin, however, is picked up by the reticuloendothelial system and converted to bilirubinglobin in the usual way¹⁷.

Figure 12 indicates that, in cases of constitutional hepatic dysfunction, the only abnormality appears to be the retention of bilirubinglobin in the blood due to functional impairment of liver cells. Bilirubinglobin does not pass the renal filter, and hence the jaundice is acholuric, as in cases due to hemolytic anemia. Red-cell destruction proceeds at a normal pace, and despite the fact that some bilirubinglobin is retained in the blood, the rates of formation and excretion of sodium bilirubinate and urobilinogen are normal or only slightly reduced²⁴.

Regardless of the cause, jaundice of the retention type is nearly always mild. The icteric index is seldom above 30 or 40, and the quantitative van den Bergh determination reveals that most of the serum bilirubin is of the indirect variety⁵.

The abnormalities of pigment metabolism that may be present in either toxic or infectious hepatitis are presented in Figure 13. Sodium bilirubinate that has regurgitated around the necrotic cells and

re-entered the blood passes the renal filter, and if sufficient quantities are excreted in the urine, one or more of the various tests for bilirubinuria are positive. Since bilirubinuria often precedes clinical

jaundice, the larger portion of the serum bilirubin is of the direct variety.¹²⁰ The amounts of sodium bilirubinate entering the intestine from the liver also vary widely, depending on the extent of cellular

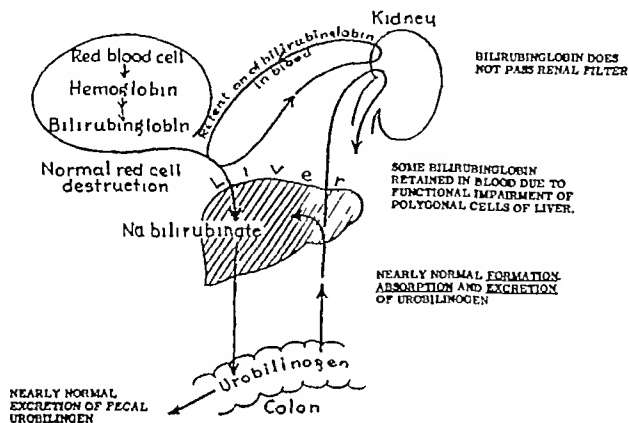

FIGURE 12. *Abnormality of Bile-Pigment Metabolism in Retention Jaundice due to Constitutional Hepatic Dysfunction.*

jaundice, the highly sensitive Harrison test is useful in screening large groups of persons who are suspected of developing hepatitis—that is, those exposed to noxious chemicals or to epidemic hepa-

necrosis and associated intrahepatic biliary obstruction and leakage from damaged cholangioles. The badly injured liver, however, cannot handle its usual large share of any urobilinogen absorbed

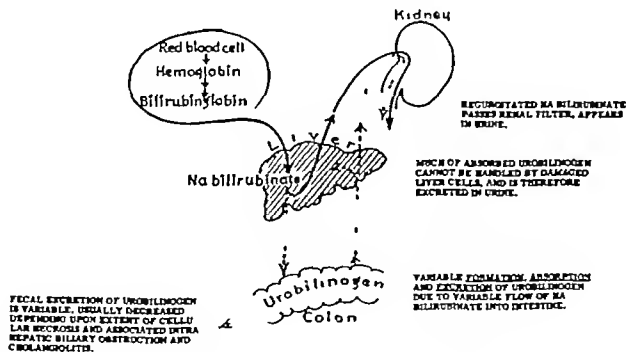

FIGURE 13. *Abnormalities of Bile Pigment Metabolism in Regurgitation Jaundice due to Hepatitis*

tus and those who have received icterogenic lots of human serum or plasma. As stated above, the quantitative van den Bergh test may give variable results in hepatitis, but at the time of maximal

from the colon, hence much of the absorbed urobilinogen is excreted in the urine.

Figure 14 serves to emphasize the fact that sodium bilirubinate that regurgitates into the blood as a

result of biliary obstruction passes the renal filter and appears in the urine, as in cases of hepatocellular necrosis. Extrahepatic block due to calculi is relatively incomplete and transient, but in about 90 per cent of cases in which malignant tumors involve the biliary tract, obstruction eventually becomes complete.¹⁵ If bilirubin cannot reach the intestine, urobilinogen formation ceases, except for the few milligrams a day that are derived from the intestinal mucosa. It has been stated that increased

seen in active cases, and pigment stones, which may eventually obstruct the common duct. Jaundice in such patients may then be attributed not only to increased bilirubin production but also to biliary obstruction and to hepatocellular damage caused by both anemia and increased biliary pressure. The multiple factors operating in hepatitis have already been enumerated.

In this admittedly incomplete formulation, the pathogenesis of jaundice has been considered only

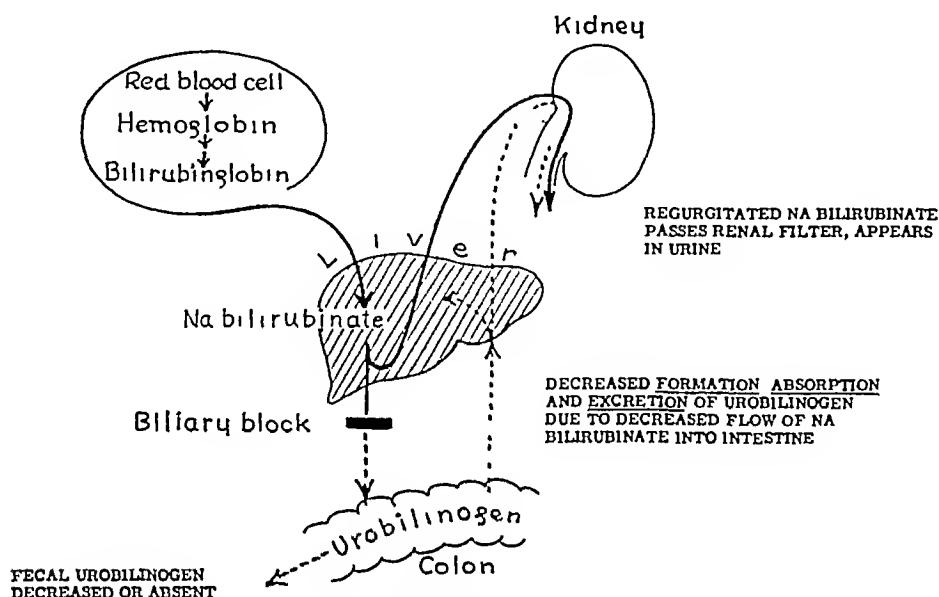

FIGURE 14 *Abnormalities of Bile-Pigment Metabolism in Regurgitation Jaundice due to Biliary Obstruction*

fecal urobilinogen excretion is the prime index of rapid erythrocyte destruction. By the same token, fecal urobilinogen excretion below 5 mg a day may be considered the most reliable indication of complete biliary obstruction.^{15, 147, 148} When examinations of consecutive four-day fecal samples indicate the persistence of complete obstruction, it is found in the great majority of cases that the patient is suffering from cancer. If little or no urobilinogen is formed in the colon, little or none is reabsorbed and consequently urobilinogen cannot be demonstrated in the urine. In the presence of complete biliary obstruction, three factors may operate to prevent the accumulation of enormous amounts of bilirubin in the serum: urinary excretion of bilirubin, decreased bilirubin formation, and bilirubin destruction.¹² The last two factors require further study.

It should be emphasized that most of the various types of jaundice cannot be placed in airtight compartments, distinct unto themselves. Patients with chronic hemolytic anemia, for example, are prone to develop plugs or thrombi of inspissated bile, which block the smaller canaliculi and which may explain the occasional rise in direct serum bilirubin

as related to laboratory tests for the various hemoglobin derivatives found in blood, urine and stool. It should be stressed that hematologic studies and the results of certain liver-function tests may also be of distinct value in differential diagnosis.¹⁴⁹⁻¹⁵¹ Perhaps the most important diagnostic problem regarding jaundice is that of distinguishing between hepatitis and extrahepatic biliary obstruction—a matter that is particularly difficult when a phase of nearly complete intrahepatic obstruction is encountered during the course of hepatitis. Operation in such cases subjects the patient to an unnecessary hazard, whereas a long delay of operation in some cases of extrahepatic obstruction may also prove disastrous.¹⁵² In the decision of such an issue, the history, physical findings and clinical course are most helpful. Repeated determinations of bilirubin in the blood and urine and of urobilinogen in the urine and stool are of distinct but nevertheless secondary value. Inasmuch as the pathologic processes responsible for jaundice are not static, it is essential that time relations be taken into consideration when the results of any laboratory procedures are interpreted. When decision regarding the etiology of jaundice is difficult, the clinician

obtains the best results by using and repeating at appropriate intervals a selected group of liver-function tests with which he is most familiar. Since surgery is likelier to be harmful than helpful in such cases, a period of observation to determine the course of the illness will usually prove to be time well spent.¹²¹

* * *

The principal objective of this presentation has been to review current concepts of the mechanisms by which jaundice may be produced. With these mechanisms in mind, it is possible to arrive at an accurate diagnosis and to prescribe treatment in most cases on the basis of repeated bedside observations and relatively simple laboratory tests. It therefore seems inappropriate in this brief treatise to present elaborate tables of differential diagnosis and a hurried resumé of current therapeutic methods. In closing, I should like merely to state that Plato's familiar words concerning the practice of medicine seem particularly applicable to the management of the jaundiced patient: "This is an art which considers the constitution of the patient and has principles of action and reasons in each case."

MASSACHUSETTS MEDICAL SOCIETY

PROCEEDINGS OF THE COUNCIL

Annual Meeting, May 19, 1947

THE annual meeting of the Council was called to order by the president, Dr. Dwight O'Hara, on Monday, May 19, 1947, at 7:00 p. m., in the Georgian Room of the Hotel Statler, Boston.

Present were one hundred and eighty-eight councilors (Appendix No. 1).

After opening the meeting the President read the following obituary notices:

ENOS HOTT BIGELOW—On March 13, 1947, past president Enos Hoyt Bigelow died in Framingham where he was born ninety-one years ago. He was educated at Worcester Polytechnic Institute and Harvard Medical School, graduating from the latter and beginning practice in Framingham in 1882.

During the sixty-odd years that Dr. Bigelow practiced medicine, he had an active interest in public affairs of many sorts. In 1912 he was elected a representative in the State Legislature and in 1914 became House chairman of the Public Health Committee from which position he rendered much assistance to the Society's Committee on State and National Legislation. In 1917 Dr. Bigelow became chairman of the Society's Committee on Public Health, a position that he held for a period of years. It is of interest that these were the years during which his son George was deciding on what was to become for him a brilliant but tragic career in public health.

Dr. Bigelow served on the Board of Health and the School Committee in Framingham; he was a trustee of the Andover Newton Theological School, a member of the American Board of Foreign Missions, president of the Boston Seaman's Friend Society, the Framingham Trust Company and the Framingham Home for the Aged. He was a councillor from Middlesex South District Medical Society for many years and was president of the Massachusetts Medical Society in 1923 and 1924. Throughout his life and well into the present decade, Dr. Bigelow faithfully attended his district society meetings and until recent years he was frequently present at the meetings of the Council.

Men like Dr. Bigelow are missed; his personality was an amiable and enthusiastic influence wherever he appeared. All of us regret his passing even as we are grateful that he was granted such a long and useful life.

HILBERT FRANCIS DAY—Hilbert F. Day for many years a councillor from the Middlesex South District Medical Society, passed away on May 16, 1947. He was sixty-eight years old.

Born in Roxbury, he graduated from Roxbury Latin School, of which he became a life-trustee, from Yale University and from the Harvard Medical School in 1905. He had for many years made his home in Cambridge.

Dr. Day held many prominent professional positions including those of senior surgeon at the Cambridge Hospital, surgeon-in-chief at the Boston Dispensary, professor of clinical surgery at Tufts College Medical School, consulting surgeon to many Greater Boston hospitals and president of the Middlesex South District Medical Society. He was a fellow of the American College of Surgeons and a diplomate of the American Board of Surgery.

Although in frail health during recent years, Dr. Day maintained a lively interest in a great variety of medical activities, including such causes as those of the Washing-

tonian Hospital, the Massachusetts Medical Benevolent Society, the Cambridge Tuberculosis and Health Association and the Family Society of Boston. His capacity to maintain these interests was an example of courage and firmness of purpose that evoked the admiration of his many friends. He will be long and well remembered by those with whom he worked.

DANIEL JAMES ELLISON—On February 15, 1947, death suddenly took Daniel J. Ellison of Lowell. Dr. Ellison was born in Rochester, New York, sixty years ago. His father before him and two of his brothers were also physicians.

He graduated from Tufts College Medical School in 1908 and subsequently served an internship at the Cambridge Hospital. He first practiced medicine in Alton, New Hampshire, moving to Lowell in 1915 at which time he was admitted to fellowship in the Massachusetts Medical Society. In Lowell, Dr. Ellison practiced continually until his death, except for a period of military service in World War I. In addition to his membership in the Society, he belonged to the American Medical Association, the American Heart Association and the New England Obstetrical Society and was a past president of the Middlesex North District Medical Society. He was a founder of the Lowell Medical Club and a staff member of the Lowell General, the St. John's and the St. Joseph's hospitals in that city. He was widely recognized and called upon in his district as a cardiologist and consultant in that field.

Dr. Ellison was a member of the Committee on Public Relations representing the Middlesex North District Medical Society and also served on several important subcommittees in connection with labor and industrial relations. He was chairman of the Subcommittee to Meet with the Medical Advisory Committee of the Industrial Accident Board. In these services Dr. Ellison could be always relied on to express himself and those he represented, incisively and with independence. He was also chairman of the Committee on Post Payment Medical Care. Altogether he was most generous of his time and energy in rendering these services to the Society.

Last February when the Council directed that its felicitations be expressed to our convalescing secretary, the mission was entrusted to Dr. Ellison, his friend and fellow townsman. Dr. Ellison responded with characteristic thoroughness and enthusiasm; it was probably his last service to the Council and one for which I fear we never thanked him for he died within the week. For his many services to the Society we are grateful.

ARTHUR WARREN HAYES—On March 11, 1947, Arthur Warren Hayes, of Greenfield, was stricken and within a few hours died at the Farnen Memorial Hospital in Montague.

Dr. Hayes was born in Lynn in 1891 and was educated at the Lynn Classical High School. He graduated from Tufts Dental School and later from Middlesex College of Medicine and Surgery. He settled in Greenfield. For twenty-two years he served on the Greenfield Board of Health and was chairman of that board. He was associate medical examiner for the Greenfield Draft Board from 1941 on.

Dr. Hayes specialized in roentgenology; he was a member of the Radiological Society of America, a diplomate of the American Board of Radiology and a fellow of the American College of Radiology. In 1942 and 1943 he served as president of the Franklin District Medical Society and had been a member of the Council since 1943.

MICHAEL ALOYSIUS TIGHE — Michael A Tighe was sixty-five years old. He graduated from Boston College in 1903 and from Harvard Medical School in 1908. He had always practiced in Lowell, where he was city physician and associate medical examiner for many years. He was a member of the American Medical Association, the American College of Surgeons and the Harvard Club of Boston. He was a past president of the Middlesex North District Medical Society, and chief of the Surgical Staff at St. John's Hospital in Lowell. He became secretary of the Massachusetts Medical Society in 1941.

When the Council last met, on February 5, we joined in extending our greetings to Dr Tighe. He responded on February 10, in part as follows: "I hope to express in person at some future time my very great appreciation of the Council's action in directing you to express its high regard for me, its sorrow at my illness and its hope for my complete and rapid recovery."

This hope was not fulfilled, for after a partial return to his accustomed activities, Dr Tighe was stricken again and died within a short time on April 8. Had it been otherwise ordained Dr Tighe would, perhaps at this very moment, express to you his appreciation of our mutual regard for him. In the realm of human relations this would be nothing less than a mirror image of his regard for each one of us. I venture to say that there is among us today no one who holds the Society in greater reverence and affection than did Michael Tighe. I feel confident that he would be proud to have us stand now in tribute to all fellows of the Massachusetts Medical Society who have died during the past year, including himself, for he was one who loved his fellow men.

The Council stood in tribute to the departed members.

The President announced the following interim appointments, which were confirmed by vote of the Council:

To the Subcommittee on Mental Health, authorized by the Council on February 5, 1947:

Walter E Barton, Norfolk
William Malamud, Worcester
Henry A Tadgell, Hampshire

To the Special Advisory Committee on School Medical Services, authorized by the Council on February 5, 1947:

Stewart H Clifford, *Chairman*, Middlesex South
Elmer S Bagnall, Essex North
Florence McKay, Suffolk
Joseph Garland, Suffolk
James O Walls, Worcester
George L Steele, Hampden
Ernest Morris, Middlesex South

To fill the unexpired term of Secretary due to Dr Tighe's death:

Joseph Garland, Suffolk

To fill the vacancy on the Council due to the death of Dr Day:

Sylvester B Kelley, Middlesex South

The Secretary submitted the record of the meeting of the Council of February 5, 1947, as published in the *New England Journal of Medicine*, April 17, 1947, and moved its acceptance. The motion was duly seconded. Before calling for a vote, the President read the following statement:

The Council will remember that the vote to support the Boston Medical Library was conditioned by two amendments to the effect that such support be legally appropriate to the purposes of the Society and that the Library be asked to indicate what services it might be able to provide the fellows of the Society in return for this support.

These conditions have been followed up to the point that we can announce that there are no legal impediments in the mind of our attorney, Mr Dodge, who has provided

a statement to this effect. We have here a copy of this statement, which may be viewed by anyone interested or may be read aloud if the Council wishes.

In regard to the second condition the Trustees of the Boston Medical Library are working on a series of suggested changes in their by-laws. These changes contemplate an increase in the number of trustees from twelve to sixteen, the four new members to be appointed by the president of the Massachusetts Medical Society. It is likewise contemplated that a new class of membership in the Library be instituted, to include every fellow of the Society in good standing, who will thus become what will be known as a Massachusetts Medical Society member of the Boston Medical Library. Just what the privileges of such membership will be cannot yet be determined, but they will certainly be no less ample than those of other existing memberships at the present time. A copy of these suggested changes as they are currently conceived by the Trustees of the Library is here and is likewise open to inspection or can be read if the Council so desires.

The report was then accepted by vote of the Council.

REPORT OF THE TREASURER

This report (Appendix No 2) was offered by the treasurer, Dr Eliot Hubbard, Jr, Middlesex South, as published in the pamphlet of advance information, with one minor correction noted in the mimeographed report of the Executive Committee. Its acceptance was moved and seconded and was so ordered by vote of the Council.

REPORTS OF COMMITTEES

Executive Committee — Dr Joseph Garland, Suffolk, *Secretary*

The Secretary submitted the report of the meeting of April 23, 1947, as circulated in mimeographed form (Appendix No 3), and moved its acceptance. The motion was seconded, and it was so ordered by vote of the Council.

Auditing Committee — Dr Howard B Jackson, Norfolk, *Chairman*, and Dr Frank T Downey, Middlesex South

The chairman being absent, this report, which is as follows, was presented by the President:

The Auditing Committee appointed the firm of Hartshorn and Walter, accountants and auditors, to audit the books and accounts of the Massachusetts Medical Society. This audit and account are hereby approved by us.

The analysis of the revenues and expenses of the Society and the balance sheet of the condition of the funds of the Society have been inspected and approved by us.

Its acceptance was moved and seconded, and it was so ordered by vote of the Council.

Committee on Arrangements — Dr Sidney C Wiggins, Suffolk, *Chairman*

The following report was presented by the chairman:

The Committee on Arrangements wishes to report on the final program for the annual meeting — May 20, 21 and 22.

We believe that an exceptionally interesting program has been arranged for the general practitioner and that the section luncheon programs will be of unusual interest and value to the specialty fields.

We wish to call your attention to the technical exhibits in the ballroom and foyer. These cover the development of many new medical supplies and equipment and much can

be gained from them. We wish to encourage the co-operation of every member of the Society in visiting these booths during the meeting, as it is the income from their rental that makes meetings such as this possible.

The medical exhibits have not come up to our expectations and we would suggest another year that special effort be made to stimulate the members of the Society and especially the hospitals to develop exhibits of their most interesting medical developments that would be of help to the general practitioner of Massachusetts.

This year the members of the Massachusetts Physicians' Art Association formerly the Boston Physicians' Art Society are having their first exhibit in conjunction with the annual meeting at the Hotel Statler. This is the first exhibit of its kind since 1938. It is being organized by Dr. James C. Janney, vice-president of the Association. This should prove of great interest to the members of the Massachusetts Medical Society and their wives.

Its acceptance was moved by the chairman, was seconded and was so ordered by vote of the Council.

Committee on Ethics and Discipline—Dr. Ralph R. Stratton, Middlesex East, Chairman.

The following report was presented by the chairman.

During the past year between fifty and sixty complaints and inquiries concerning ethical procedures have been received by the committee, necessitating much investigation and six all-day and two special sessions of the committee.

There have been rather more inquiries as to ethics and procedures this year than usual coming from all parts of the Commonwealth, indicating a more healthy ethical sense on the part of the members at large.

Several fellows have been deprived of membership in the Society because of the decisions of the State Board of Registration of Medicine and Chapter 1, Section 9, of our by-laws. This separation has been without any loss to the efficiency and dignity of the Massachusetts Medical Society.

Numerous run-of-the-mill complaints have been received and investigated. Following conversations with the chairman several of these complaints have been withdrawn. The others have been investigated and viewed by the committee and settled on their merits without any loss of prestige to the fellow and with greater or less satisfaction to the complainant.

A number of complaints against fellows of more serious nature have been received and investigated. These included such complaints as unethical advertising, serious neglect in the care of a patient by the physician and overcharging for value received. All these cases have been investigated, reviewed and settled by the committee. Space does not allow further elaboration.

Two cases, however, must be discussed. The first is a complaint of fellow against fellow for definite violation of the Code of Ethics in his treatment of the other fellow's rights. The fellow was found guilty of deliberate violation of the code, was reprimanded by the committee, ordered to apologize to the offended fellow and referred to the President for censure. A copy of an apology was received by the committee, the President notified us that the censure had been applied and the case was considered closed.

In the second case, a physician complained that a fellow used language at a public hearing derogatory to his reputation and standing as a physician, which language unfortunately was published in the newspapers. In conversation with the chairman the fellow offered to apologize to the offended physician, the committee accepted this offer and requested the fellow to send an apology to the offended physician and forward a copy to the committee. Upon receipt of this apology the matter was considered closed.

The committee was unhappy and somewhat concerned at the receipt of these two apologies, for while they were apologies they were couched in such language that the committee felt that in neither case did the fellow show any penitence for his deed. The committee will watch with interest the future ethical observances of these two fellows, that of the first because during his interrogations he showed

a definite ignorance of what constitutes ethical conduct and that of the second because of his apparent indifference to the code by reason that this is the second time within a comparatively few months that he has been obliged in apology to a fellow for unethical acts.

In this connection the Committee on Ethics and Discipline calls attention to the following circular, which has been prepared under the auspices of the supervising censors.

Attention of the Candidate

When you are admitted to membership in the Massachusetts Medical Society, you will be supplied with its Code of Ethics and with the Principles of Medical Ethics of the American Medical Association to all of which you shall be required to subscribe.

You are urged to study this code and these principles to the end that you may conduct your professional life in a manner befitting an honorable physician.

So that you may have some preliminary knowledge in this subject the supervising censors submit to you at this time a brief summary of these requirements.

You shall be required to regard the welfare of your patients as taking precedence over your own comfort or your financial or other material gain.

They shall receive at your hands thorough examination and sympathetic treatment of their ills. You shall make due allowance for their peculiarities.

The seal of secrecy shall govern your relations with them to be broken only in accordance with the civil law of the Commonwealth or on the direct order of the civil authority.

Their ailments, therefore, shall not be the subject of gossip.

You shall encourage sound medical learning as the *sine qua non* of good medical care and as a corollary of this you shall distinguish between legitimate medicine and quackery and have no part or interest in the development or distribution of secret remedies.

You shall call attention to your professional qualifications only by the performance of work well done.

You shall not seek professional advantage at the expense of a fellow practitioner. Honor and courtesy shall govern your relations with him.

You shall not by actual act or by innuendo seek to divert another's patient to yourself.

The practice of fee splitting is forbidden in any guise whatsoever.

It will be your obligation to contribute your time and energy to the end that the Massachusetts Medical Society may continue to represent the ideals of the medical profession.

Inquiry has revealed the fact that a supply of these circulars has been distributed to the district secretaries by the Secretary with the direction that each applicant be handed a copy with his application, that he be examined on its contents and that the censors determine his fitness for membership to a large extent by the answers that be gives.

The Committee on Ethics and Discipline recommends that the Council by its vote give further emphasis to the importance of this procedure and that the Secretary be instructed to so notify the district secretaries.

The acceptance of the report was moved by the chairman. The motion was seconded and it was so ordered by vote of the Council.

Dr. Stratton then went on to call to the attention of the Council the recommendation that the Committee on Ethics and Discipline was making concerning the notice that had been drawn up by the supervising censors and was presented to each candidate for admission to the Society. He said that it was

the belief of the committee that this notice should be given the approval of the Council, because after its perusal no candidate could come into the Society without a working knowledge of the *Code of Ethics* of the Society and *Principles of Medical Ethics* of the American Medical Association. It was brought out by Dr Stratton that in the last few years a number of cases have come before the committee in which the offending fellow had apparently no acquaintance with the *Code of Ethics* and knew nothing about ethical procedure with regard to his relations with his fellows. This synopsis of the *Code of Ethics* constitutes part of the material on which the candidate is examined by the censors of his district.

Dr Stratton then read the recommendation of the committee and moved its adoption, to give emphasis to the *Code of Ethics* of the Society. The motion was seconded.

Dr Carl Bearse, Norfolk, offered as an amendment to the motion that a copy of the notice also be sent to every member of the Society with the next general mailing. After some discussion the amendment was adopted.

Dr Stratton moved the adoption of the recommendation as amended. The motion was seconded, and it was so ordered by vote of the Council.

Committee on Public Relations—Dr Albert A Hornor, Suffolk, *Secretary*

This report, which follows, was presented by the President. It is divided into three items, which were recommended for acceptance by the Executive Committee.

1 The Subcommittee on Insurance Relations, which was appointed in accordance with the direction of the meeting of the Council in October, 1946, made the following report to the Committee on Public Relations:

The committee is aware of the desire and interest of the American Medical Association in the development of plans for prepayment medical care throughout the United States. Several years ago the Massachusetts Medical Society took steps aimed at the provision of prepayment medical care for the people of Massachusetts and has placed in operation a plan to effect this idea. This program has now been subscribed to by over half a million people in this state and is rapidly increasing in its acceptance by the public.

This committee feels that any plan aimed at extending the opportunity for prepayment medical benefits to the residents of this State is commendable.

HAROLD G GIDDINGS

A J A CAMPBELL

NORMAN A WELCH

DONALD MUNRO, *Chairman*

This report was accepted and approved by unanimous vote of the Committee on Public Relations.

The Committee on Public Relations recommends that this report be accepted and approved by the Council and that the subcommittee be discharged.

2 In accordance with the instructions of the Council at its February meeting in 1946, the Committee on Public Relations has studied the question of establishment of a women's auxiliary to the Massachusetts Medical Society. This has been reported on three times by the subcommittee, consisting of Dr Milton J Quinn, chairman, Dr Harold R Kurth and Dr Albert A Hornor.

At the November meeting of the Committee on Public Relations each district society representative on the Committee on Public Relations was directed to bring the opinion of his respective society to the next meeting of the Committee on Public Relations.

At the meeting March 19, 1947, reports from eleven district societies were recorded, as follows: five in favor, four opposed and two no action. The Committee on Public Relations recommends:

That the Council extend to each district the privilege of forming, at the district's pleasure, a women's auxiliary. That the Council authorize the Committee on Public Relations to aid in the organization of these said units.

3 As a report of progress the Committee on Public Relations submits the following items:

The establishment of a Speaker's Bureau was discussed. Dr John Conlin, who was present as a guest, told us that when he began to work he wanted to be able to come to the committee for help and guidance. The problem was discussed freely by all present and it was decided that each member of the Committee on Public Relations would come to the next meeting prepared to discuss this question with Dr Conlin.

Dr Harold R Kurth, representative of the Essex North District Medical Society, made the following report:

At a meeting of the Essex North District Medical Society there was considerable discussion between the members of the society and Mr R F Cahalane, director of the Blue Cross, with reference to the payment of anesthetist's fees by the Blue Cross. Under the present ruling the Blue Cross pays anesthetist's fees only to those individuals who are regularly employed as anesthetists by the hospitals.

It is the feeling of the members of this district that this present arrangement prevents many private physicians who give anesthesia to Blue Cross patients from being paid an anesthetist's fee, simply because they are not regularly employed as such by the hospital, whereas the regularly employed anesthetist of the hospital is paid. In some cases these regularly employed anesthetists are merely nurses, trained in anesthesia.

Therefore, the Essex North District Medical Society presents the following resolution to the Massachusetts Medical Society, namely:

That the whole question of the payment of anesthetist's fees by the Blue Cross be reconsidered.

This report brought general discussion of the subject of the relation of the members of the Massachusetts Medical Society to the Blue Cross and the Blue Shield. It was moved by Dr Charles D McCann, Plymouth, and seconded by Dr Kurth that the chair appoint a committee of three to investigate this problem and report at the next meeting of the Committee on Public Relations, if necessary having a special meeting to discuss these problems. The committee was instructed to get from each member of the Committee on Public Relations his ideas of the problems presented and what should be done about them.

This motion was passed unanimously and the chair appointed, as members of that committee, Dr Kurth, Dr McCann and Dr Albert A Hornor.

The first item comprises the report of the Subcommittee on Insurance Relations and contains the recommendation, "Any plan aimed at extending the opportunity for prepayment medical benefits to the residents of this state is commendable."

Dr Bagnall, Essex North, in discussion, questioned the wisdom of such an inclusive endorsement of prepayment medical benefits and moved that the report be returned to the subcommittee for further study. This motion was seconded.

Considerable discussion was participated in by Drs William E Browne, Suffolk, Donald Munro, Suffolk, Frank R Ober, Suffolk, and Peirce H Leavitt, Plymouth. Dr Leavitt offered as an amendment to Dr Bagnall's motion that "any plan aimed at extending the opportunity for prepayment medical benefits to the residents of this state may be commendable." This amendment was seconded.

Dr Sosman, Suffolk, offered a further amendment to make the last sentence of the report read

This committee feels that any plan which conforms to the basic principles adopted by the Society in regard to medical-service plans and which is aimed at extending the opportunity for prepayment medical benefits to the residents of this state is commendable.

This amendment was seconded. After further discussion, the question was put to vote and Dr Leavitt's amendment was defeated. Dr Sosman's amendment was then put to vote and adopted by the Council, after which the recommendation as a whole was adopted.

The second item in the report of the Committee on Public Relations concerns the establishment of a women's auxiliary within the Society. The committee report recommended action by the Council to permit the establishment of women's auxiliaries within the district societies and to authorize the Committee on Public Relations to aid in the organization of these units.

Dr Milton J Quinn, Middlesex East, spoke in favor of the recommendation so convincingly that Dr Bearse, Norfolk, offered the following amendment, "In addition to the districts being privileged to form these women's auxiliaries, there also be established a women's auxiliary to the Massachusetts Medical Society." This motion was seconded by Dr Quinn and was so ordered by the Council.

The main recommendation of the committee, to permit the establishment of women's auxiliaries within the districts, was then put to vote and was so ordered by the Council.

The remainder of the report of the Committee on Public Relations gave information on two points, first, the establishment of a speakers' bureau, and second, a discussion that had taken place within the Essex North District with reference to the payment of anesthetist's fees by the Blue Cross.

President O'Hara, in mentioning this part of the report, made the Council aware of action that would be asked of the Council on this subject later in the meeting.

The entire report of the Committee on Public Relations was then accepted by the Council.

Committee on Legislation—Dr George R Dunlop, Worcester, Dr David L. Belding, Norfolk South, Co-chairmen.

The following report was offered by Dr Dunlop.

Since the opening of the 1947 session of the Massachusetts Legislature in January there has been one meeting of the committee and three meetings of the executive subcommittee, at which a total of thirty-seven bills has been considered. It has been voted to favor seven, oppose thirteen, and take no action on nineteen of these bills. The 'no action' bills have been chiefly concerned with general sanitation departmental activities and economic problems not intimately connected with the practice of medicine. Favorable action has been taken on five bills of the Massachusetts Department of Public Health, the one concerning blood tests in illegitimacy (H. 145) and that covering tuberculosis in school teachers (H. 705).

The bills opposed by your committee are those that lower medical standards and limit medical practice and research. The important chiropractic bill (S. 151) was given leave to withdraw by the Legislative Committee on Public Health at the request of the petitioners. S. 26 and H. 974 for opening hospitals to all physicians have been successfully opposed. H. 1211 which would lower standards for licensed attendants has been withdrawn. H. 706 relating to the College of Physicians and Surgeons H. 633 regarding the unionization of hospital employees H. 541 revoking certain powers of medical examiners and three minor bills have been opposed. The antivivisection bills (S. 47, H. 126 and H. 1361) were reported unfavorably by the Legislative Committee on Legal Affairs. Opposition was efficiently handled by a special Committee on Antivivisection with members from the three Massachusetts medical schools, the Massachusetts Medical Society and the Associated Catholic Hospitals.

At the February meeting the Council voted that the Committee on Legislation aid in expediting Dr Gettlog's program for (1) raising the salary level of the professional personnel engaged in public health on a state or local basis, (2) instituting a sanitary code, (3) providing subsidization of local health departments, and (4) promoting town unions of adequate size to support a modern public and school health program. The last two topics are not under consideration by the Legislature this year. Your committee has favored the sanitary-code bill (H. 78). It has presented to Governor Bradford the recommendation of the Massachusetts Medical Society that the professional salaries in the Department of Public Health and the Department of Mental Health be placed at levels that will allow Massachusetts to compete with outside agencies. It has also obtained the co-operation of the *New England Journal of Medicine* in publishing an editorial on this subject.

On March 27, Dr Bagnall, chairman of the Subcommittee on National Legislation and the official representative of the Council, appeared before the Senate Committee on Expenditures in the Executive Departments at Washington and recorded the opposition of the Society to S. 140 and S. 712, bills creating a tripartite department of health, education and security. The Subcommittee on National Legislation finds that the Taft Bill (S. 545) in general conforms to the principles established by the Massachusetts Medical Society but that certain minor changes are necessary to make it acceptable. The Committee on Legislation will present the views of the Society before the appropriate committee when hearings on the bill are held at Washington.

The announcement by Dr Dunlop that all thirteen bills opposed by the committee were rejected by the Legislature was greeted with applause.

Of the seven bills favored, one was enacted and among the four rejected was H. 78, on the sanitary code, which the Council had favored at the February meeting. Two bills, that for licensing of hospitals and the bill requiring x-ray examination of chests of schoolteachers, were still in committee. The report was accepted by the Council.

Committee on Medical Defense — Dr Arthur W. Allen, Suffolk, *Chairman*

The following report was offered by Dr Allen

We now have seven cases pending. During the past year, we have disposed of three suits — one of these was dismissed for lack of prosecution and the other two were settled out of court.

Five new cases have been added during the past year. This is a definite increase over recent years. We believe that some of these will not be brought to trial for lack of evidence. One or two of them may prove to be quite troublesome.

There has been increasing difficulty in obtaining satisfactory expert witnesses for the defense of our fellows. Councilors are urged to assist our attorneys in these matters whenever possible. Many members of the Society have given freely of their time and advice when called upon.

The charges for legal services for the past year amounted to \$1,167.75. This represents the entire expenditure of this committee.

Dr Allen moved the acceptance of the report. The motion was seconded, and it was so ordered by vote of the Council.

Committee on Publications — Dr Richard M. Smith, Suffolk, *Chairman*

This report (Appendix No. 4) was submitted as published in the circular of advance information. Dr Smith moved its acceptance. The motion was seconded, and it was so ordered by vote of the Council.

Committee on Veterans' Affairs — Dr G. Philip Grabfield, Suffolk, *Chairman*

This report is as follows:

The committee has held no formal meetings since our last report because no questions have been referred to it and none of the members had any suggestions to make on which action was necessary. It appears that most of the immediate veteran's problems have been considered and solved in so far as it was possible for the Society to do so. The committee is unanimous in feeling that any committee that has no work to do should be dissolved and yet it is hesitant about a firm recommendation to terminate its existence due to the doubt that exists as to the possibility of further veterans' problems being brought before the Society.

It is therefore recommended that the Veterans' Committee remain in existence until after the annual meeting in 1947 in order to deal with any veterans' problems that may come up at that time and that if no such problems appear at the annual meeting the committee be discharged.

The President, in commenting on this report, called the attention of the Council to the action of the Executive Committee regarding it. The Executive Committee viewed with some concern the continuing complications in the present relations between the Society and the Veterans Administration and on that account recommended the omission of the part of the report calling for the discharge of the committee after the annual meeting. This recommendation was accepted, and the report as thus amended was accepted by vote of the Council.

Committee to Confer with the Massachusetts Farm Bureau Federation — Dr Joseph C. Merriam, Middlesex South, *Chairman*

The following report was offered by Dr Merriam:

This report is informational. Through the chairman of this committee the headquarters of the Massachusetts Farm Bureau was notified that the committee had been appointed and was ready to meet with them to discuss any medical problems they may have and to help them in any way within its power.

The chairman was assured by the Farm Bureau that they had no medical problems but should any arise the committee would be notified.

Dr Merriam moved the acceptance of this report. The motion was seconded, and it was so ordered by vote of the Council.

Committee to Survey Salaries — Dr Charles J. Kickham, Norfolk, *Chairman*

The following report was offered by Dr Kickham:

This committee, which was ordered by the Council to consider a retirement plan, has met and after consideration has found that the problem is very complex. We have to give consideration to the age limits, the cost, the amount of compensation to be received at retirement and many other details.

The committee unanimously agreed that considerable time would be necessary before any decision could be made and that we should have one or more plans submitted to us by competent insurance companies to guide us in our study. It was felt that this would take months and consequently at this time we simply submit a report of progress.

Dr Kickham moved the acceptance of this report. The motion was seconded, and it was so ordered by vote of the Council.

Committee to Aid the Regional OPA — Dr Joseph Garland, Suffolk, *Chairman*

The following report was offered by Dr Garland:

This committee was appointed at the annual meeting of the Society in 1943 to advise the Regional Office of Price Administration on the medical aspects of food rationing. During the war years and so long as active rationing continued, its duties were considerable and their performance of some possible value to the war effort. For over a year the occasional rationing problems have been confined to the dispensing of sugar.

As of June 30, 1947, the Office of Price Administration goes out of existence and your committee, desiring not to outlive its usefulness by too long, requests that it also be discharged.

Dr Garland moved the acceptance of this final report and the discharge of the committee. The motion was seconded, and it was so ordered by vote of the Council.

Report of the Committee to Meet with General Hawley — Dr Humphrey L. McCarthy, Norfolk, *Chairman*

This report (Appendix No. 5) was submitted as published in the circular of advance information. Dr McCarthy, in presenting the report, explained the difficulties that had been encountered in attempting to co-operate with the Veterans Administration through a Blue Shield contract. These difficulties were based largely on the opposition of the American Legion and the Veterans of Foreign Wars to two bills filed by Blue Shield and Blue Cross which would allow these organizations to sign con-

tracts with a federal or local agency. As stated in the report of the Executive Committee (Appendix No. 3) these bills were reported three times unfavorably by the Insurance Committee of the Legislature, making it impossible to continue with the Blue Shield contract. Dr. McCarthy accordingly recommended a new type of program in which the Society would deal directly with the Veterans Administration under a gentleman's agreement, similar to the so-called "Kansas Plan."

To facilitate this change in policy the Executive Committee recommended three actions by the Council:

(1) To remove from the table, where it was placed by vote of the Council on October 2, 1946, the recommendation of the Executive Committee that the vote of the Council of April 10, 1946, in special meeting be rescinded. (This vote adopted the plan of a contractual arrangement between the Veterans Administration and the Blue Cross-Blue Shield whereby the hospital expenses of veterans in civilian hospitals would be met by the Blue Cross as agent and whereby the costs of professional services of civilian physicians caring for veterans under the fee schedule would be met by the Blue Shield as agent.)

This was moved by Dr. McCarthy, the motion was seconded, and it was so ordered by vote of the Council.

(2) To rescind the vote of April 10, 1946.

This was moved by Dr. McCarthy, the motion was seconded, and it was so ordered by vote of the Council.

(3) To refer the whole matter back to the Committee to meet with General Hawley for further negotiations along the lines of a gentleman's agreement and report to the Council.

This was moved by Dr. McCarthy, the motion was seconded, and it was so ordered by vote of the Council.

Dr. McCarthy then moved the acceptance of the entire report. The motion was seconded, and it was so ordered by vote of the Council.

On motion from the floor, unanimously carried by the Council, Dr. McCarthy was given a vote of thanks for "the enormous amount of work that he has put into this program, is putting in and will probably continue to put in."

Committee on Postgraduate Instruction—Dr. W. Richard Ohler, Norfolk, Chairman.

This report (Appendix No. 6) was submitted as published in the circular of advance information. In presenting it, Dr. Ohler pointed out that it also included a report of the Bureau of Clinical Information.

The report contained one recommendation, that the program as carried on last year, which includes the Sanders Theater Exercises, be continued another year.

President O'Hara, in commenting on this recommendation, noted that the instruction sponsored by the committee, figured on the basis of the usual col-

legiate semester hours, amounted to a complete college course given for thirty or forty men, all in one year.

The recommendation was carried, after which the acceptance of the report as a whole was moved by Dr. Ohler. The motion was seconded, and it was so ordered by vote of the Council. Dr. O'Hara's expression of the Council's gratitude to Dr. Ohler was greeted with applause.

Joint Committee on Rehabilitation and Industrial Health—Drs. Daniel Lynch, Norfolk, and Joseph H. Shortell, Suffolk, Chairmen.

The following report was offered by Dr. Lynch:

On April 2, 1947, there was a joint meeting of the Committees of Industrial Health and Rehabilitation. Present for the Committee of Industrial Health were Drs. Daniel Lynch, chairman, Harold R. Kurth, Louis Daniels, and Thomas Shipman. Present for the Committee on Rehabilitation were Drs. Joseph Shortell, chairman, Ralph Chambers, James Regan, Arthur Watkins, and members *ex officio*: Drs. Dwight O'Hara and Edward F. Bagg. As guest advisers were Drs. Henry Marble, Alexander Altken, director of the Liberty Mutual Rehabilitation Clinic, Mrs. Emma Tossant, member of the Industrial Accident Board, and Mr. Herbert Dallas, Division of Vocational Rehabilitation.

The whole field of rehabilitation was discussed and particularly Dr. Augustus Thorndike's request as to whether there is need for a community rehabilitation center and service in Boston. Dr. Thorndike was present and fully explained the proposed establishment of a rehabilitation clinic.

It was resolved that the joint Committee of Rehabilitation and Industrial Health agrees that there is a definite need for the establishment of a community rehabilitation center and service in Boston in accordance with the Report of the Baruch Committee on Physical Medicine, but that it should be established, maintained and controlled locally and not nationally, and that such a project is advisable.

Dr. Lynch moved the acceptance of the report.

President O'Hara then asked Dr. Augustus Thorndike, Suffolk, to discuss the report, since the consideration of a community rehabilitation center had resulted from a resolution presented by him at the February meeting of the Council.

Dr. Thorndike, in discussion, explained that what is planned by the Baruch Committee on Physical Medicine would not proceed without the approval of the Society, and would be a nonprofit organization with outpatient and consultation service for the physically handicapped, where doctors and hospitals could refer their patients for late convalescent care. Such a clinic would be available to all economic classes. At present, to the best of Dr. Thorndike's knowledge, the Liberty Mutual Rehabilitation Clinic is the only medically supervised center in New England.

Dr. Donald Munro, Suffolk, in emphasizing the point that the economic status of the patient was not a matter of consideration, explained that only through such a clinic could certain types of patient, such as those with paralysis from spinal injuries, receive proper care.

Drs Lynch and Arthur L Watkins, Middlesex South, spoke further in support of the establishment of such a center

The motion to accept the report was seconded, and it was so ordered by vote of the Council

Committee on Physical Medicine—Dr Arthur L Watkins, Middlesex South, *Chairman*

The following report was offered by Dr Watkins

This committee has had no new work assigned to it, but would like to make an informational report on activities in physical medicine in this area. The Veterans Administration has established a far-reaching plan for medical rehabilitation in all its hospitals. This includes physical and occupational therapy, physical rehabilitation and shop and educational retraining, all under the direction of a specialist in physical medicine termed a physiatrist. This program aims to carry the patient through the convalescent or third stage of medical care and guide him toward suitable employment.

The plan for a New England rehabilitation center for civilian casualties of disease and injury recognizes a similar need for more complete medical care during convalescence, particularly employing physical medicine, including evaluation for employment capabilities.

The recent literature in physical medicine has again been reviewed and will appear in the *Journal* as a progress report entitled "Recent Trends in Physical Medicine."

Dr Watkins moved the acceptance of the report. The motion was seconded, and it was so ordered by vote of the Council.

Dr Paul R Withington, Norfolk, having raised a question as to the formation of women's auxiliaries, Dr O'Hara put to a vote the question of returning to the report of the Committee on Public Relations for further discussion. This was not carried.

Committee on Nominations—Dr Ralph R Stratton, Middlesex East, *Chairman*

In the absence of Dr Stratton, Dr Allen G Rice, Hampden, presented the following supplementary report of the committee

A special meeting of the nominating councilors, called by President Dwight O'Hara, was held Wednesday, April 30, 1947, at 4 00 p m in the Prince Room, 8 Fenway, Boston.

The untimely death of the Secretary, Dr Michael A Tighe, and the withdrawal by Dr Edmond F Cody of his nomination for vice-president left these positions unfilled. At this special meeting the nominating councilors nominated for secretary Dr Joseph Garland, Suffolk, and for vice-president Dr Charles J Kickham, Norfolk.

The slate of the nominating councilors is therefore amended to read as follows

President-elect	Daniel B Reardon
Vice-president	Charles J Kickham
Secretary	Joseph Garland
Treasurer	Eliot Hubbard, Jr
Assistant treasurer	Norman A. Welch
Orator	Allen S Johnson

The President asked for nominations from the floor. There being none, Dr Rice moved that the Secretary be instructed to cast one ballot for the list of officers as submitted by the Committee on Nominations. This motion was seconded, and it was so ordered by vote of the Council.

This vote having been cast, the President announced that the list of officers as read had been elected.

President O'Hara then introduced Dr Edward P Bagg, president of the Society for the 1947-1948 term of office, as follows

Dr Bagg, last year Dr Fitz presented me with ten volumes of the proceedings of the Society, each one autographed by the president of that year, for ready reference of the president, and you will find those, sir, in the presidential desk at 8 Fenway. You will also find there an eleventh volume, which is the proceedings of the Society for 1946 and inscribed by Dr Fitz, to carry on the tradition that he commenced.

I have at this time the honor to present to you, which Dr Fitz presented to me, the presidential copy of *Robert's Rules of Order* and the keys to the Society. They will let you in at 8 Fenway, where you may wander at will. We welcome you into your presidency, sir.

Dr Bagg made the following reply

Dr O'Hara, I thank you for these donations, which are much needed. I don't know about the keys, but *Robert's Rules* will have to be my constant companion, I can see. If we can only emulate the example that has been set us this year with a modicum of success, I shall be satisfied. That is not a mere chance remark, either. As you know, Dr O'Hara has put a great deal of time and thought into these meetings, and one of the reasons they have moved along so successfully is that he knew the agenda and he knew what the Executive Committee had discussed.

It has been a privilege this past year to sit in with these committees and see them function and to learn the personalities involved, and I feel better prepared tonight than I did a year ago. But I know I shall need all your assistance.

We shall miss Dr Tighe greatly. As Dr O'Hara has told you, there are very few members who have had such a warm interest in the affairs of the Society.

I think this might be the proper occasion to tell you about a rather dramatic episode. Dr O'Hara and I had talked things over after Dr Tighe's first attack, and we had decided that it was too much for him to undertake the secretaryship and private practice. So I wrote him a letter asking him if he would care to have me bring in a resolution suggesting that the secretaryship should be made full time, because we felt that he should not jeopardize his health with general practice. I wish you could have seen the expression on his face as he sat there. He was delighted beyond words and overcome with the suggestion and said he would go home and think it over. I had a letter from him several days later stating that after prolonged thought, for it was not an easy decision, he had decided to accept if the Society felt that they wanted him for full time service. And then of course he ended, "And I am delighted to say that I am sound again and ready for work." But five days later he was called to other fields. It is at least, however, a great satisfaction to me to think that he had that one joyous experience. The question whether the position should be made full time can wait and need not be discussed this evening, but at least I do not regret having written that letter. We shall go into that some time at length.

But once more, gentlemen, let me thank you for the honor. I will do my best to live up to the privileges as well as the responsibilities.

Dr Daniel B Reardon, Norfolk South, president-elect, was then escorted to the platform and introduced to the Council. Dr Reardon addressed the Council as follows

I wish to thank each and every one of you individually for having elected me to the office of president-elect. I shall now take Dr Bagg's position as a sitter for the next year, and I expect to gain considerable profit in occupying that position.

I am thoroughly familiar with many of the committees because I have served on a good many of them so some of their work will not be new to me. I accept this offer with a keen appreciation of the responsibility which it holds. I do it with a sense of deep humility. My earnest endeavor shall be to serve you and to serve the Society as well as possible and at all times to maintain the dignity and honor of that office. Thank you

After the introduction of the remainder of the slate of officers elected, the President called for new business to come before the Council, as the president-elect was not at the moment prepared to submit his list of committee appointments

NEW BUSINESS

Dr Merrill C Sosman, Suffolk, rose to present a joint resolution by the roentgenologists, pathologists and anesthesiologists of Massachusetts. As a preliminary explanation he reminded the Council that the Blue Cross had just sold a comprehensive, all-inclusive contract at a per-diem rate, and he stated that the three groups mentioned had objected to it on three principles first, that it includes medical services as hospital care, second, that it puts the hospital in the bad situation of "holding the bag" with an unpredictable amount of insurance, as Blue Cross has guaranteed to cover all x-ray charges regardless of cost, but pays for them only on a per-diem rate, and third, that it puts control of the professional services more into lay hands than it has been before

Dr Sosman then presented the following resolutions

WHEREAS, Massachusetts Hospital Service agreements which affect the professional status of pathologists, radiologists, and anesthesiologists have been offered to the public and hospitals without consultation with representatives of the organizations of these specialists in Massachusetts, and

WHEREAS, Radiology (sometimes referred to as roentgenology or x-ray examination, diagnosis or treatment) pathology (sometimes referred to as laboratory examination or diagnosis) and anesthesiology constitute the practice of medicine and are medical services and

WHEREAS, The House of Delegates of the American Medical Association on June 8 1943, recommended

That the House emphatically reiterate that it disapproves the injecting of a third party into the personal relationship of the patient and the physician and that hospitals should not be permitted to practice medicine.

That the practice of radiology pathology and anesthesiology is the practice of medicine just as much as is the practice of surgery or internal medicine, and that it is only a short step from including the first three in a medical service plan to including the whole field of medicine in such a plan, and

WHEREAS, We are heartily in accord with the basic principle of insurance against the cost of sickness and hospitalization by voluntary prepaid plans in accordance with the principles adopted by the Massachusetts Medical Society, and

WHEREAS, The proposed over-all comprehensive Massachusetts Hospital Service agreement on a per diem basis of compensation fails to distinguish between hospital services and professional medical services, such as pathology x ray and anesthesia and

WHEREAS, The proposed Massachusetts Hospital Service agreement on a per diem basis submerges completely the

professional standing of the services of the pathologist, radiologist and anesthesiologist and relegates them to a hospital service similar to room board and drugs, and

WHEREAS, The introduction of the proposed per diem plan which includes professional services will undoubtedly lead to an unpredictable increased volume of work, especially in radiology and could result in control of professional services by hospital administrators, thus lowering the quality of the work with the inevitable danger to the public welfare and

WHEREAS, At the present time there is a shortage of well trained pathologists radiologists and anesthesiologists in this country and whereas an important factor in this shortage is the tendency for hospitals to minimize the professional standing of these specialists and thus not attract the best class of physicians to these specialties and furthermore a per diem basis of payment will certainly increase this trend so that these specialties may lose their standing as professional specialties therefore be it

RESOLVED, That the New England Pathological Society, the New England Roentgen Ray Society the Section of Radiology of the Massachusetts Medical Society the New England Society of Anesthesiologists and the Section of Anesthesiology of the Massachusetts Medical Society oppose any arrangement by any hospital with the Massachusetts Hospital Service that will allow this organization to guide or determine professional services and furthermore be it

RESOLVED, That the New England Pathological Society the New England Roentgen Ray Society the Section of Radiology of the Massachusetts Medical Society the New England Society of Anesthesiologists and the Section of Anesthesiology of the Massachusetts Medical Society oppose the principle of the over all comprehensive Massachusetts Hospital Service Agreement on a per diem basis of compensation because it fails to distinguish between hospital services and professional medical services such as pathology, x ray, and anesthesia and furthermore be it

RESOLVED, That they recommend that charges for all professional services performed by physicians should be specifically excluded from all hospital service plans

The New England Pathological Society the New England Roentgen Ray Society the Section of Radiology of the Massachusetts Medical Society, the New England Society of Anesthesiologists, and the Section of Anesthesiology of the Massachusetts Medical Society recommend

That the logical organization to write insurance against professional charges is the Blue Shield rather than the Blue Cross and that these two organizations attempt to work out a method of collaboration to cover these items.

That since contracts including professional services have been sold, it is proposed as an interim arrangement that charges for these professional services be billed directly by the hospital to Blue Cross and per diem rates be appropriately reduced by quota to compensate for this amount.

Since this contract was to go into effect on June 1, Dr Sosman moved that Rule 1 of the Council, requiring all new business offered at Council meetings to be referred to a committee, be suspended, as provided for by Rule 3. The motion was seconded.

President O'Hara referred the resolution to the Committee on Public Relations, because that committee already had a subcommittee working on the anesthesiologists' aspect of the problem. He then called for discussion of the motion to suspend the Council rule. After considerable discussion by Drs Bagnall, Sosman and Schadt, the motion was passed.

Dr Sosman then moved that the Council approve the resolutions presented by the New England Pathological Society, the New England Roentgenological Society, the Section of Radiology of the Massachusetts Medical Society, the Section of

Roentgenology of the Massachusetts Medical Society, the New England Society of Anesthetists, and the Section of Anesthesiology of the Massachusetts Medical Society. The motion was seconded, and the Council voted to approve the resolutions.

Dr Bagnall then moved that this whole matter be re-referred to a subcommittee of the Committee on Public Relations to be appointed by the President for a thorough study and report to the Council. The motion was put to vote and failed to be approved by the Council.

Dr Charles J Kickham, Norfolk, newly elected vice-president, having returned to the meeting, was introduced to the Council by the President and addressed the Council as follows:

I apologize for being out of the room when I understand that I was called to be presented before you. While I had only been vice-president of the Society at that time a matter of about five minutes, I had already learned definitely (which I knew before) that I was a subordinate because Dr Bagg had requested that I leave the room and talk with him for a few minutes, which I did.

I appreciate the honor of being vice-president of the Society, not only personally, but because I know that I represent here as vice-president the Norfolk District Medical Society, which I have always been associated with and of which I am deeply fond. I trust that if there is anything I can do as vice-president to be helpful to Dr Bagg, he will request it. As I said a moment ago, I appreciate the honor, but also I assure you I realize its limitations. Thank you.

The President called on Dr John E Moran, Franklin, to report for a committee consisting of Drs Moran, Henry A Taddell, Hampshire, and Joseph Garland, Suffolk, appointed to draw up a resolution for presentation to the Council, stating the problem of sex criminality in Massachusetts and the need for its study.

Dr Moran presented the following resolution:

WHEREAS, This committee has been appointed by the president of the Society to draw up a resolution for presentation to the Council relative to "sexual psychopaths" and the problem of sexual psychopathy within the Commonwealth, and

WHEREAS, We as a committee recognize sexual psychopathy to be a condition wherein there is basically a constitutional personality defect frequently manifest by overt acts of a vicious nature against society, and

WHEREAS, We are of the opinion that the problem is not exclusively medical but is in large measure sociologic and penologic, therefore be it

RESOLVED, That the Massachusetts Medical Society take cognizance of the problem of sexual psychopathy and indicate its desire to co-operate, in any reasonable manner, in a study of the matter, and be it further

Resolved that a copy of this resolution be sent to the Recess Commission appointed to study the question of sexual psychopaths.

President O'Hara referred the resolution to the Committee on Mental Health, a subcommittee of the Committee on Public Health.

Dr Curtis C Tripp, Bristol South, presented the following letter from Dr David L Belding, Norfolk South, to the President:

The shortage of nurses has become one of the most pressing problems of present-day medicine. It is of vital importance to hospitals and private physicians. As such

it would seem to be the responsibility of the Massachusetts Medical Society to make a thorough study of this critical situation in order to formulate possible plans for its solution.

I am therefore asking you to present this matter to the Council, under "New Business" in order that, if the Council so decides, it may be referred for study to the appropriate committee.

Dr Tripp moved that this matter be referred to a committee by the President. The motion was seconded and carried, and the matter contained in Dr Belding's letter was referred to the Committee on Medical Education and Diplomas.

Dr Reginald Fitz, Suffolk, was recognized and moved that the President be authorized to appoint a committee to study the problems suggested by the resolution presented by Dr Sosman and report back to the Council. The motion was seconded.

Dr Sosman offered as a substitute motion that the President appoint a special committee, to include representatives of the Blue Cross, the Blue Shield, the Massachusetts Hospital Association, the Massachusetts Medical Society, the radiologists, the pathologists, the anesthesiologists and any other specialty groups concerned to define hospital services and medical services and to establish the proper relations between physicians and hospitals.

Dr Fitz having accepted this substitute motion, it was put to vote and was so ordered by vote of the Council.

COMMITTEE APPOINTMENTS

The President-Elect submitted a list of nominations to committees for the year 1947-1948. It was moved and seconded that the nominations be confirmed, and it was so ordered by vote of the Council.

There being no further business before the Council, the President declared the meeting adjourned at 10:30 p.m.

JOSEPH GARLAND, *Secretary*

APPENDIX NO 2

TREASURER'S REPORT

Return of members from the armed forces has been reflected in the increased income from dues during 1946 to \$51,752 from \$39,325 in 1945. Nonresident dues rose from \$1500 to \$1776. Income from the *New England Journal of Medicine* was \$9000 this year as compared with \$22,800 last year due to the mounting costs of publication. Income from censors fees rose from \$474 to \$1242, an indication that more new applicants are seeking membership in the Society. The Committee on Arrangements turned in an excess of income over expenses from the annual meeting of \$5268 and the New England Postgraduate Assembly a similar excess of \$323.

The Endowment Fund's income rose from \$498 to \$503 and the General Fund's from \$4527 to \$5162 but the Building Fund dropped from \$2156 to \$1989. This can be attributed in the call of certain securities bearing a higher rate, or to their sale, in anticipation of call, to realize a better market price and to the sale of a few long term bonds to reinvest in convertible bonds of lower interest rate with an eye toward greater possibilities of profit in the future through their conversion features. However, in the Building Fund profit on sale of securities rose to \$391 in 1946 from \$173 in 1945, and profit from sales in the General Fund rose from \$991 to \$1898. The amount received from subscriptions to the *New England Journal of Medicine* from men in service fell from \$1312 to \$622, this total was paid over to the *Journal*.

Changes in the holdings of the General Fund resulted from the sale at profit of a number of separate bond issues of small denominations and reinvestment in larger unit holdings of two new bond offerings, both convertible into common stock—Dewey & Almy Co. 2 1/4's due 1976, and American Telephone and Telegraph Co. 2 1/4's due 1961. The following preferred stock shares were purchased during the year—50 shares U S Steel Cn 7 per cent cumulative, 100 shares Atlantic Refining Co. 4 per cent cumulative and 90 shares Monsanto Chemical Co. 3 1/4 per cent cumulative convertible.

The General Fund securities now represent a book value of \$179,094 as compared with \$142,689 in 1945.

The Building Fund securities stand at a book value of \$69,665, as compared with \$68,027 in 1945.

The Endowment Fund securities remain at the same book value as last year, \$23,166.

In summary, total revenue in 1946 was \$78,072 and total expenses \$52,046 leaving an excess of revenue over expenses of \$26,026.

Total Building Fund assets amount to \$73,117 an increase over last year of \$2580.

General Fund assets amount to \$238,152, an increase of \$26,953 over last year.

The Society ends 1946 with a grand total of assets in cash and securities of \$334,436 an increase of \$29,533 over 1945.

A breakdown of comparative expenses in 1945 and 1946 is appended. It is obvious that there has been a steady increase from \$33,133 in 1945 to \$52,046 in 1946 and a budget of \$64,195 for 1947. Plans are being considered which may well raise the annual expense figure for 1948 to over \$100,000. This makes an increase in the dues imperative.

It is hoped that with an increase in dues the Society will consider a larger refund to the district societies annually and also that, under guidance of the Committee on Finance the Society may consider pegging the total assets of the General Fund at a certain maximum figure and that, in any given year, after all expenses have been paid any income raising the General Fund above this figure be automatically diverted into the Building Fund. There is little to be gained by

indefinitely enlarging the General Fund, whereas the Building Fund stands not only for a potential much needed headquarters, but once the property has been acquired, stands back of it as an endowment, the income from which can be used to support the running of the establishment.

The year 1946 marks the ending of a long era of pleasant association between the Treasurer's Office and the staff of the *New England Journal of Medicine*. Now that the Society has developed its own clerical staff, the Treasurer would like to emphasize his appreciation for all past kindnesses and help given him by the *Journal* personnel.

APPENDIX NO 3

REPORT OF THE EXECUTIVE COMMITTEE

The Executive Committee of the Council met on April 23, 1947, in Sprague Hall, 8 Fenway, Boston, the meeting being called to order at 4 15 p.m. Dr Dwight O'Hara, president of the Society, was in the chair.

Dr O'Hara spoke feelingly of the loss of Dr Tighe, secretary of the Society, on April 8, and asked those present to stand for a moment in silent tribute.

The record of the last meeting as submitted by the Secretary was then approved.

COMMITTEE REPORTS

Committee on Membership

This report, which had been circulated in mimeographed form, under date of March 19, was acted on by sections and accepted by unanimous vote.

Committee on Nominations

Dr O'Hara, referring again to the death of Dr Tighe, announced that he had appointed Dr Joseph Garland to fill Dr Tighe's unexpired term and had asked the Committee on Nominations to meet again on April 30 to propose names for secretary and vice-president, Dr Edmond F Cody having declined the latter nomination.

Treasurer's Report and Report of the Auditing Committee

Dr Eliot Hubbard, Jr, treasurer called attention to an error. The sentence reading "Total Building Fund assets amount to \$73,177, an increase over last year of \$2640," should read "— an increase over last year of \$2580." The Executive Committee recommends the adoption of this report as corrected, including the report of the Auditing Committee.

Committee on Ethics and Discipline

This report, for information only, is recommended for adoption by the Council. The Executive Committee commends the circular prepared under the auspices of the supervising censors for the instruction of candidates.

Committee on Public Relations

This report is divided into three items, the first two of which contain recommendations.

The first, a report of the Subcommittee on Insurance Relations, was accepted by the Committee on Public Relations, which recommended its acceptance by the Council, and the discharge of the subcommittee. The Executive Committee recommends the acceptance and approval of this report by the Council.

The second item concerns the establishment of a women's auxiliary to the Massachusetts Medical Society by the districts, at their pleasure, with the Committee on Public Relations aiding in the organization of these said units. The Executive Committee recommends that the Council accept this recommendation.

The third item concerns (a) the establishment of a Speaker's Bureau and (b) a discussion that took place at a meeting of the Essex North District Medical Society with reference to the payment of anesthetist's fees by the Blue Cross.

The Executive Committee recommends that the report as a whole be accepted by the Council.

Committee on Veterans' Affairs

In view of the continuing complications in the present relations between the Society and the Veterans Administration, the Executive Committee recommends the omission of the lines in this report calling for the discharge of the committee after the annual meeting.

Committee to Meet with General Hawley

It has become recently apparent that the method of co-operating with the Veterans Administration through a Blue Shield contract has been blocked, as the Massachusetts Medical Service does not deem it wise to handle this type of contract under existing conditions. As noted in the committee report, bills (H 950 and 137) filed by Massachusetts Medical Service and Blue Cross have been opposed by the American Legion and the Veterans of Foreign Wars, and reported three times unfavorably by the Insurance Committee.

The chairman of the Committee to Meet with General Hawley, Dr Humphrey L McCarthy, therefore recommends that the Massachusetts Medical Society deal directly with the Veterans Administration under a gentleman's agreement, similar to the Kansas Plan, rather than with a formal contract. To re-open this matter, three motions are necessary.

(1) To remove from the table, where it was placed by vote of the Council on October 2, 1946, the recommendation of the Executive Committee that the vote of the Council of April 10, 1946, in special meeting, be rescinded. (This vote adopted the plan of a contractual arrangement between the Veterans Administration and the Blue Cross—Blue Shield, whereby the hospital expenses of veterans in civilian hospitals would be met by the Blue Cross as agent and whereby the costs of professional services of civilian physicians caring for veterans under the fee schedule would be met by the Blue Shield as agent.)

(2) To rescind the vote of April 10, 1946.

(3) To refer the whole matter back to the Committee to Meet with General Hawley for further negotiations along the lines of a gentleman's agreement, and report to the Council.

The Executive Committee recommends to the Council the adoption of these three motions.

Committee on Postgraduate Instruction

The Executive Committee calls special attention to the great service that this committee has rendered and recommends that its work be enthusiastically endorsed.

Joint Report of Committees on Rehabilitation and Industrial Health

The recommendation of these committees reads as follows: It was resolved that the joint Committee of Rehabilitation and Industrial Health agrees that there is a definite need for establishment of a community rehabilitation center and service in Boston in accordance with the Report of the Baruch Committee on Physical Medicine but that it should be established, maintained and controlled locally and not nationally, and that such a project is advisable.

The Executive Committee recognizes the desirability of such a rehabilitation center and recommends the acceptance of the committee report, with the suggestion that it be discussed before the Council by some authoritative individual.

OTHER BUSINESS

On motion of Dr. John E. Moran, Franklin President O'Hara appointed a committee consisting of Drs. Moran, Henry A. Taddell, Hampshire, and Joseph Garland, Suffolk, to draw up a resolution for presentation to the Council stating the problem of sex criminality in Massachusetts and the need for its study.

On motion by Dr. Kickham, the Executive Committee tendered to Dr. O'Hara a vote of thanks for the wisdom and celerity with which he had conducted its meetings during the past year.

The Executive Committee adjourned at 5:45 p.m.

JOSEPH GARLAND
Secretary pro tempore

APPENDIX NO. 4

REPORT OF THE COMMITTEE ON PUBLICATIONS

The Committee on Publications wishes at this time to report upon its supervision of the publication of the *New England Journal of Medicine* for the year 1946. We quote from the report of the managing editor, Dr. Robert N. Nye to the committee:

During the year 1946 the *New England Journal of Medicine* continued to expand, and the new regular and student subscriptions and the net gain in circulation were larger than ever before, the respective figures being 6783 and 3296, as compared with 5913 and 3203 in 1945. Since there were 4729 new regular subscribers and 823 transfers from "student" to "regular" but a net gain of only 2308 this means that the inscriptions of 3244 were canceled during the year. The loss of approximately 1000 of these subscribers is accounted for by canceled subscriptions from the Army and Navy, but that of the balance remains unexplained. Incidentally, the gain from the discharge of members of the Society from the armed forces about balanced the loss of Army and Navy subscriptions. As of December 26, 1946, *Journals* were being sent to 5380 members of the Society, 12,074 regular subscribers (including some members of the New Hampshire Medical Society), 3302 medical students, 345 members of the New Hampshire Medical Society (monthly), and 283 miscellaneous readers—a total of 21,384 copies, as compared with 18,088 at the end of 1945.

Publication costs were markedly increased during 1946, whereas the total cost which includes printing,

binding, mailing and paper stock, was about \$76,500 in 1945 it increased to \$120,500 in 1946. Fortunately the revenue from advertising increased from \$75,900, to \$93,300 and that from subscriptions from \$66,300 to \$84,800 almost covered the greater publication cost, with the result that the *Journal* was able to pay to the Treasurer on December 31, 1946, the sum of \$9000, as compared with \$22,800 at the end of 1945. Since no money was advanced to the *Journal* by the Treasurer during 1946, this represents a clear profit. The actual profit was \$11,300, the balance being represented by an increase in surplus from \$15,800 to \$18,100.

During 1946, the editorial board considered 292 manuscripts, of which 201 or 69 per cent, were accepted. The corresponding figures in 1945 were 203 and 129.

Book paper is still scarce and of poor quality in fact, it is scarcer and of poorer quality than at any time during the war. In spite of the shortage, however, the number of text pages in 1946 was 1,834 compared with 1,508 in 1945. The reproduction of cuts has left much to be desired, but nothing can be done about it until a higher grade of paper is available. The majority of roentgenograms should be printed on coated stock, but this cannot be obtained. It is hoped that the paper situation will have improved by the end of the current year.

Although copies of the *Journal* are usually delivered to this office on the day following the date of publication, binding and mailing result in a delay of six or seven days before copies are received by members of the Society. This is unfortunate but practically unavoidable. In due course, it may be possible to cut the period to three or four days. The delay in the delivery of reprints is not so long as it was in 1945 but is still much longer than it should be possibly this can be corrected.

The decision of the Massachusetts Medical Society to employ its own stenographers has relieved the office staff of much work that interfered with an orderly routine. Furthermore, this has resulted in more office space for the work of the *Journal*. This increased space will suffice for a year or so, but even now hall again as much space is really needed. Telephone calls for the Society are still handled by the office staff, and since these comprise more than half the incoming calls, it seems only reasonable that, with an office force of its own the Society should have a separate switchboard.

Robert O'Leary has returned to his former position as one of the assistant editors after three and a half years in the Army. The relief of the managing editor is unbounded! Miss Davies and her staff have continued to handle the affairs of the *Journal* in a manner that is irreproachable.

The outlook for 1947 appears reasonably good. An abundance of manuscripts seems assured which permits the editorial board to exercise even higher standards of acceptance. An increase of circulation is anticipated particularly student subscriptions, inasmuch as a student representative of the *Journal* has been appointed in nearly all approved medical schools. A survey is now underway to determine, if possible, why a certain number of regular readers fail to renew their subscriptions. The cost of publication will be higher since the charges for printing, binding and mailing are to be increased 15 per cent on April 1 and the rates for paper have risen following the removal of ceiling prices. Advertising rates were increased on July 1, 1946 and on January 1, 1947 but since it is customary to permit all regular advertisers to continue for a year at former rates, the full effect of these increases will not be realized until after January 1, 1948.

An abstract of the auditors' reports is appended. The full report, signed by the auditors Hartshorn and Walter, is in the hands of the treasurer of the Society.

The Committee again records its deep appreciation of the services of Dr. Nye. His management of the *Journal* has given to the Society a publication of which it may justly be proud.

OLIVER COPE
JOHN FALLON
JAMES P. O'HARA
CONRAD WEISELHOFF
RICHARD M. SMITH, Chairman

APPENDIX NO 5

REPORT OF THE COMMITTEE TO MEET WITH GENERAL HAWLEY

Last December, Part I of the fee schedule for medical services to the Veterans Administration was accepted and turned over to the Massachusetts Medical Service and signed as a contract. Since that time many things have happened

- 1 In the original plan, the procedure was to be as follows. The veteran requests treatment from the Veterans Administration in person or by letter, phone or telegram. If the Veterans Administration has no facilities available or if it would cause undue hardship for the veteran to report to a Veterans Administration facility, an authorization is sent to the Massachusetts Medical Service. The Massachusetts Medical Service issues a letter of eligibility to the veteran showing the number and type of treatments authorized. The veteran presents the letter of eligibility to any participating doctor. The doctor treats the veteran. At the end of month the doctor completes the treatment report and forwards a portion of the letter of eligibility to the Massachusetts Medical Service. The Massachusetts Medical Service pays the doctor if in order, and forwards the report of treatment to the Veterans Administration. At the end of month the Massachusetts Medical Service bills the Veterans Administration on a master voucher.
2. During the first part of December, 1946, approximately 6000 registration forms were sent to physicians in Massachusetts asking whether they desired to participate in the plan and whether or not their practice was chiefly concerned with a specialty. An analysis of the registration is as follows

CLASSIFICATION	CERTIFIED*	IN PROCESS	TOTAL
Allergy	8	3	11
Anesthesia	31	11	42
Cardiology	6	0	6
Dermatology and syphilology	33	5	38
Diabetes	4	0	4
Diseases of chest	12	2	14
Gastroenterology	5	3	8
General practice	1423	43	1466

*Certified as a specialist only for the purpose of the Veterans Administration

3 On March 13, 1947, a letter from the Veterans Administration requested the Massachusetts Medical Society to assist the Veterans Administration in establishing for examination and treatment a list of specialists who meet the qualifications for specialists of the Veterans Administration. These qualifications were entirely new, and for those not possessing specialty-board certificates, the letter stated that the following data should be given

- The number of years of experience in a given specialty (including recognized residencies),
- The percentage of practice devoted to a given specialty and whether the physician was recognized as a practicing specialist by the Society.

4 Within the past month, Massachusetts Medical Service has filed a bill (H 950), with a companion bill (H 137) under the name of Blue Cross, to give the combined agencies the privilege to sign contracts. Both these bills have been opposed by the American Legion and the Veterans of Foreign Wars, and reported three times unfavorably by the Committee of Insurance. Many conferences have been held with Blue Shield, the Veterans Administration and the veterans' organizations, as well as your committee, and the bill was rewritten (H 950) and has been agreed on by these various organizations and is now being considered in the House.

The outcome of this bill is not known, but the committee hopes that some pertinent information will be at hand in time for the Executive Committee. If Blue Shield is not granted this special power, they feel that they will not be able to handle this contract soundly.

Your committee is now working on a new type of program, which is a modification of the Kansas Plan, to have in readiness if the Massachusetts Medical Service deems it unwise to handle this type of contract.

The type of authorization that is being formulated cuts the paper work for the doctor to one page, but cannot be publicized until the contract is in effect.

5 On March 15, 1947, the committee received a new fee schedule from the Veterans Administration (No 10-2535a), which contains the maximum fees that the Veterans Administration will pay. No previous edition should be used.

APPENDIX NO 6

REPORT OF THE COMMITTEE ON POSTGRADUATE INSTRUCTION

Up until the present year, the activities of the Committee on Postgraduate Instruction have been part of the more widespread work of the Committee on Postwar Planning. For this reason, it has not been possible heretofore to present anything more than a mere outline of the work of this committee. Consequently, in order to bring all councilors up to date, the following brief historical review is presented.

In the spring of 1945, it was voted by the Committee on Postwar Planning (a) to provide postgraduate medical instruction for all Massachusetts physicians without charge and to arrange teaching schedules so as to make it unnecessary for any physician to travel more than a few miles, (b) to divide the state into teaching districts or circuits and to carry on identical programs in all teaching hospitals in any given district, and (c) to carry on in any given district under the guidance of a local committee.

On the basis of the above plan, the Commonwealth was subdivided into teaching circuits as follows: District No. 1—Pittsfield, Great Barrington, North Adams, District No. 2—Springfield, Holyoke, Northampton, Greenfield, District No. 3—Worcester and surrounding territory, District No. 4—Fitchburg, Gardner, Leominster, District No. 5—Lowell, Haverhill, Lawrence, Newburyport, District No. 6—New Bedford, Fall River and the Cape, District No. 7—North Shore and District No. 8—Greater Boston Area.

In attempting to satisfy the wants of the Greater Boston Area and with special reference to the needs of returning veterans, the Sanders Theater program was evolved. It is not necessary to review the history of the first Sanders Theater program given in the spring of 1946 all are agreed that it was a great success. Between 800 and 900 doctors registered for the series of lectures, and the average attendance for each exercise was about 400.

It is a pleasure at this point to direct attention to the fact that the concept of the Sanders Theater course came from Dr. Lewis Hurxthal. In addition, Dr. Hurxthal did most of the work in organizing the first program and in arranging for the many details involved in any such series of exercises.

In so far as the district programs for the 1945-1946 period are concerned, exercises were given in all districts with the exception of the Pittsfield and Fall River areas, Districts 1 and 6 respectively.

In retrospect, the year 1945-1946 was a period of trial and error but a year with enough success to justify going ahead. It took personal trips to all sections of the Commonwealth to set up local committees and to sound out the ideas of various groups. It also took many meetings of the committee to work out the details. But despite difficulties and certain errors in planning the concept of offering to various districts a series of exercises so planned as to make possible discussions by a team of instructors and to cover the Greater Boston Area with a series of lectures at Sanders Theater gained support and favor.

So much for past history. The work of the Committee on Postgraduate Instruction for 1946-1947 can be presented briefly as follows:

District Programs

- District 1 (Pittsfield, Great Barrington, North Adams) — three exercises, eight instructors.
- District 2 (Springfield, Holyoke, Northampton, Greenfield) — three exercises, nine instructors.
- District 3 (Worcester and surrounding territory) — two exercises, six instructors.
- District 4 (Fitchburg, Leominster, Gardner) — three exercises, eight instructors.
- District 5 (Lowell, Haverhill, Lawrence, Newburyport) — three exercises, nine instructors.
- District 6 (New Bedford, Fall River and the Cape) — three exercises, nine instructors.
- District 7 (North Shore) — six exercises, twelve instructors.

Unfortunately we have no detailed account of the total number of physicians reached by these district programs. We can say that all exercises have been extremely well attended and, in addition, that many graduates of substandard schools have accepted this opportunity to take part in graduate study.

Sanders Theater Exercises

As before, these meetings were under the able management of Dr. Hurxthal and his subcommittee. A series of ninety-two exercises were given by ninety-four instructors, covering a period of eight weeks. Total enrollment for the series was 1240 and the average attendance well over 500.

In other words, during the 1946-1947 season throughout Massachusetts not including Sanders Theater, a series of twenty-three exercises have been presented by sixty-one instructors. If we add to this the Sanders Theater exercises then the grand total for 1946-1947 is one hundred fifteen exercises conducted by one hundred fifty-five instructors. This is offered to the physicians of Massachusetts, including doctors in the armed services and residents and interns in various hospitals by the Massachusetts Medical Society in co-operation with the Massachusetts Department of Health—all without charge.

Budget and Expenses

All instructors are paid. Those who take part at Sanders Theater receive \$10 an exercise, and those who give instruction away from Boston receive \$25 for the first exercise and \$15 for subsequent exercises, the total amount for any one day not to exceed \$55 plus expenses. The budget allowed for 1946-1947 was \$3750 exclusive of the budget for the Bureau of Clinical Information. The Massachusetts Department of Public Health, after consultation with the committee regarding subject matter of certain programs, has been able to contribute \$1100 toward the work of postgraduate instruction. With this help we are sure to finish the year well within the total amount available.

Bureau of Clinical Information

The Bureau of Clinical Information has continued to flourish under the able direction of Miss Mary D. Gaston. Although the service rendered to returning medical officers has naturally lessened, those who do seek aid present problems that are increasingly difficult to solve. The matters of location, office space, home, equipment and hospital facilities are much less easy to answer than they were a year ago and if information of this sort could be made available to the Bureau by the district medical societies a more efficient job could be done in placing the right man in the right place. On the other hand, a number of men have been placed as a result of inquiries received from an industrial firm, summer camps, a university state departments and town selectmen.

An increasing number of visiting physicians have made use of the Bureau. Indeed during 1946 physicians from twenty states and territories and from twelve foreign countries were interviewed.

The circulation of the *Bulletin* markedly increased nearly 9000 copies having been distributed as compared with about 5500 in the preceding year. Although these are most frequently used by individual physicians, many copies are forwarded to local and outlying hospitals and agencies. The *Bulletin* now lists monthly, quarterly and yearly meetings and all secretaries of medical clubs, associations and societies are earnestly requested to forward to the Bureau the dates and places of such meetings. Many conflicts of dates could be avoided if the *Bulletin* were consulted or the Bureau so informed.

Recommendations for 1947-1948

So far as can be determined the present plan of postgraduate instruction has met with considerable favor. It is not contended that the plan is ideal. It is believed by the committee, however, that enough improvement can be made under the present organization to justify a continuation of the district programs for another year. Concerning the Sanders Theater exercises, no one has the answer. It was thought by many that this year's attendance would be less than that of last year. Such has not been the case. It is entirely possible that, with continued improvement, the Sanders Theater idea may become a fixture in the scheme of postgraduate instruction. At any rate in view of this year's experience, the committee feels entirely justified in recommending that these programs be continued another year.

CASE 33341

PRESENTATION OF CASE

An eighty-six-year-old woman entered the hospital because of vomiting.

For one year prior to admission the patient had had recurrent bouts of abdominal pain and vomiting, each lasting about a day. These became increasingly frequent until, after a particularly severe attack five weeks before admission, the patient entered another hospital, where a barium enema was said to have been negative. No gall-bladder or gastrointestinal x-ray films were taken. She had suffered from dyspnea, orthopnea and ankle edema for five months. She was discharged on digitalis and ferrous sulfate. The patient felt well until two days before admission to the Massachusetts General Hospital, when she experienced a recurrence of the vomiting, the next day she began to have severe cramping pain across the abdomen, with no radiation. There were no chills or fever, no rectal bleeding and no change in bowel habits. The appetite had been poor.

A bilateral salpingo-oophorectomy, appendectomy and removal of a uterine fibroid had been performed in 1901.

Physical examination revealed a debilitated, moderately dehydrated, ill appearing woman. The heart was enlarged, with a soft systolic murmur at the base. Occasional rales were heard at the lung bases. The abdomen was diffusely tender, particularly in the right upper quadrant. There was no spasm. The liver edge could be felt two fingerbreadths below the costal margin.

The blood pressure was 158 systolic, 60 diastolic.

Examination of the blood disclosed a white-cell count of 16,500, the urine contained an occasional white cell and many granular casts. A blood Hinton test was negative. The nonprotein nitrogen was 72 mg and the total protein 6.7 gm per 100 cc, and the chloride 106 milliequiv per liter. A chest plate showed dorsal scoliosis on the right and clear lung fields, the heart was at the upper limit of normal in size but was displaced to the left, and the aorta was calcified and tortuous. A film of the abdomen showed arthritis of the lumbar spine, a small amount of gas in the bowel without dilatation, no soft-tissue

masses or unusual areas of calcification and no free air under the diaphragm.

During the night the patient developed marked abdominal pain and tenderness and generalized spasm. Pelvic examination also showed diffuse tenderness. On the second day the patient became disoriented and had to be restrained. The temperature, which had previously been normal, rose to 102°F, the pulse to 100, and the respirations to 45. A stool specimen gave a ++ guaiac reaction. Some purulent exudate was recovered on abdominal tap, which on smear showed gram-positive cocci and bacilli. The patient was given penicillin, streptomycin, fluids and oxygen but continued to fail, dying on the third hospital day.

DIFFERENTIAL DIAGNOSIS

DR. PETER SARRIS: This eighty-six-year-old woman had had recurrent attacks of abdominal pain for a year. The attacks were often preceded by vomiting. In the differential diagnosis of an acute abdomen we realize that the history plays the most important role, and one tries to select the details that will give the clues to the final diagnosis. The age of the patient might influence us in the final diagnosis by making certain diseases less likely. Conversely, the age might confuse the case in that the history as given by an aged person is not always reliable. Also, one must bear in mind that a lesion is much likelier to be fatal at that age than in a younger person and in a shorter interval of time.

Important points are that the attacks were rather distinct, lasting about a day, and that the patient was apparently fairly well between attacks. It is stated, however, that she was debilitated. That may have been because of her age, the accumulated result of the insults produced by each one of these attacks or the progression of the underlying disease. No mention is made of the amount or character of the vomitus.

The severe attack five weeks prior to entry sheds some light in that the patient apparently recovered spontaneously and was well enough to be sent home. Presumably, then, the correct diagnosis was not made at that time, unless they thought that she could not stand surgery in spite of a correct diagnosis.

A barium enema was negative, and no Graham test or gastrointestinal series was done.

No mention is made about the red-cell count or hemoglobin or about anemia. The fact that the patient was discharged on digitalis and ferrous sulfate, however, indicates that the disease was associated with anemia.

The character and location of the pain are helpful, suggesting peristaltic pain across the abdomen, and either large-bowel or small-bowel spasm, or even biliary colic could have been responsible.

The absence of chills and fever or of rectal bleeding is helpful only in a negative way, and I do not

know whether the statement "no change in bowel habits" means during the attacks only.

We must accept the fact that a bilateral salpingo-oophorectomy and appendectomy had been performed, so that those organs can be eliminated as a direct cause of the disease. With the background of a previous operation, the story suggests small-bowel obstruction. A previous operation is, of course, not necessary for that diagnosis, since one third of all cases of small-bowel obstruction are not preceded by surgery.

The dyspnea, palpitation and ankle edema can be dismissed. They are significant but not so far as the diagnosis is concerned. They undoubtedly played a part in hastening death, but could not account for this picture. The blood pressure on admission indicates that the patient was not in shock—at least, the blood pressure was not remarkable. The white-cell count was 16,500, which is not helpful in the differential diagnosis. There were granular casts in the urine but no mention of albuminuria. I always thought that any number of granular casts should be accompanied by albuminuria, that also is not helpful in the differential diagnosis. The non-protein nitrogen of 72 mg per 100 cc could have been a result of a combination of nephrosclerosis and dehydration in a patient of that age but is not of specific help otherwise.

The chest film does not help. The plain film of the abdomen was negative so far as positive findings are concerned, I had hoped that we should get more evidence from it. There was a small amount of gas in the bowel. If it was in the large bowel, it means nothing, but in the small bowel, even though it is a small amount of gas, it may be significant, particularly if in repeat films the gas has increased. I should like to see the x-ray films. I see that a tube was put down, although the record does not mention that there was gastric drainage or what was obtained and how much.

Dr STANLEY M. WYMAN: I believe that the gas lies in the small bowel, there are several loops of bowel in the left upper quadrant. They are at the upper limits of distention to be called definitely normal. It is more consistent with a picture of ileus. There is unusual calcification in the right upper quadrant.

I believe that that may well lie in the pleural cavity. That fact is not mentioned in the record, but it should have been. There is an unusually tortuous line of calcification in the right upper quadrant that is probably vascular, and slight calcification in the right upper quadrant seen below the large arc is about the expected location of the gall bladder. It suggests previous biliary disease, but it is not definite.

Dr. SARRIS: Is there any evidence of gas in the biliary tree?

Dr. WYMAN: I do not see any.

Dr JOSEPH C. AUB: What is the dense area to the right of the tube?

Dr. WYMAN: I think that that is a fold of bowel.

Dr. SARRIS: There are no signs of gallstones throughout the gastrointestinal tract?

Dr. WYMAN: I do not see any.

Dr. SARRIS: Dr. Wyman's statement that there was gas in the small bowel bordering on the abnormal is helpful. It is important to know whether it was taken on admission or on a later day.

Dr. TRACY B. MALLORY: It was taken on the day of entry.

Dr. SARRIS: The final significant point is that an abdominal tap produced purulent material that on smear showed gram-positive cocci and bacilli, thus confirming the diagnosis of purulent peritonitis. Purulent peritonitis from an infarcted solid organ occurs late in the disease, and for that matter with a solid tumor, or a cyst twisting on its pedicle, the symptoms of infarction occur first and are followed by progression with secondary infection. I believe that the peritonitis came from a rupture of a hollow viscus—not from a perforated ulcer or perforated malignant tumor of the stomach, because I cannot visualize such distinct attacks caused by carcinoma of the stomach or attacks lasting only a day by an ulcer. The crampy nature of the pain is against that diagnosis, although pyloric stenosis occurs with crampy pain, preceded by vomiting.

Mesenteric thrombosis is fairly frequent at this age, ending with peritonitis, but it is not likely in this case because of the duration. It often causes premonitory symptoms, with minor attacks weeks before the final one, from thrombosis of minute vessels. I have not seen a case with distinct attacks for such a long period, and I believe that mesenteric thrombosis can be dismissed. Regional enteritis producing final perforation and peritonitis can also be discarded because the attacks were of such short duration. Acute mechanical small-bowel obstruction with strangulation is more difficult to dismiss. Recurrent attacks are not unusual, but I think that this patient had too many attacks for that. Usually, patients with acute small-bowel obstruction from adhesions—due either to a congenital band or to previous surgery or a Meckel's diverticulum—have only one or two preceding attacks and then get into trouble from gangrene. Carcinoma of the large bowel I shall dismiss, since there was no recorded change in bowel habits and the process was not progressive enough. Vomiting is not a prominent feature of carcinoma of the large bowel except late in the course of the disease. Carcinoma of the cecum can be associated with anemia but does not produce obstruction with obstructive pain, except terminally.

If this patient had had a Meckel's diverticulum, the chances are that it would have been discovered at the previous operation. Diverticulitis is a frequent cause of peritonitis in this age group, although

vomiting is seldom a prominent symptom of diverticulitis, which usually starts with fever. This patient was afebrile, and the attacks were of short duration.

Volvulus, particularly in the sigmoid, ends up with strangulation, infarction and peritonitis, but this patient had had too many attacks over a year for volvulus, the vomiting was too prominent, and the bowel symptoms were absent. The x-ray picture is not that of volvulus of the sigmoid. Recurrent intussusception from a small-bowel tumor such as a polyp is a definite possibility. Against it, however, is the fact that when a patient dies from one of these tumors with intussusception the evidence of small-bowel obstruction preceding it is much more definite than in this case. The intussuscepted bowel produces obstruction for a long enough time to cause dilated bowel before the infarction goes on sufficiently to perforate the bowel. I cannot exclude that diagnosis, however.

Biliary-tract disease must be seriously considered. The frequency of attacks of colic suggests a common-duct stone, especially in this age group. In younger patients recurring attacks of gallstone colic result from stones only in the gall bladder, but my experience has been that in older people when the disease is limited to the gall bladder it is frequently associated with perforation. If this patient had biliary-tract disease with such recurrent attacks, with a state of well being between attacks, common-duct stone would be the diagnosis. Although there were no chills, fever or jaundice, I cannot believe this woman had frequently recurrent gallstone colic from stones only in the gall bladder ending in an attack with perforation of that organ. One must assume common-duct stones along with it.

Gallstone ileus is a definite possibility because it accounts for the recurring attacks. These attacks could have been caused by either common-duct stones or the passage of many stones from a cholelithoduodenal or choledochojunal fistula, with crampy pain and vomiting. Finally, a large stone came down and bobbed around in the small bowel. There is evidence that it could finally have grown larger from the fecal concretions, and then produced the obstruction followed by perforation and peritonitis. The only thing against that is the fact that when gallstones perforate and cause general peritonitis, they are preceded for some time by intestinal obstruction.

Finally, carcinoma of the small bowel is rare, but whatever this patient died of is also probably infrequent. Of course, the fact that one expects an unusual case at these exercises does not justify the making of a rare diagnosis. The recurrent attacks are characteristic of cancer of the small bowel, which is a difficult diagnosis to make preoperatively. Vomiting preceding pain is a common story. Anemia, which I assume this patient had, is consistent with carcinoma. The lack of bowel symptoms

is more consistent with a small-bowel than with a large-bowel lesion. In the former the higher the lesion, the likelier it is to be carcinoma, and the lower down the likelier to be sarcoma.

I believe that this woman had general peritonitis from perforation of a hollow viscus. That is as far as I can go with any degree of certainty. To go beyond that and try to state the cause of the perforation one would have to resort to guesswork. Is there any description of blood cells in the aspirated fluid?

DR MALLORY: They are not mentioned.

DR SARRIS: In purulent peritonitis secondary to infarction there are numerous red cells along with the pus and bacteria.

I shall conclude by saying that my first diagnosis is carcinoma of the small bowel, with perforation and the second choice is biliary-tract disease, with gallstone ileus and perforation.

CLINICAL DIAGNOSES

Perforated viscus (? stomach or gall bladder)
Generalized peritonitis

DR SARRIS'S DIAGNOSIS

Carcinoma of small bowel, with perforation?
Biliary-tract disease, with gallstone ileus and perforation?

ANATOMICAL DIAGNOSES

Carcinoma of gall bladder, with perforation
Cholelithiasis
Choledocholithiasis
General peritonitis
Arteriosclerosis, generalized
Calcereous aortic stenosis
Hypertrophy of heart
Nephrosclerosis

PATHOLOGICAL DISCUSSION

DR MALLORY: This was obviously a difficult case. The clinicians did not commit themselves any farther than a perforated viscus. Dr Sarris pointed a finger of suspicion to the biliary tree and also mentioned a carcinoma as a likely possibility, but he did not put the two together. That combination is what was found, however. The patient had a carcinoma of the gall bladder. Carcinoma of the gall bladder is found almost invariably in patients who have had gallstones for years. There were a great many stones within the bladder. A perforation had developed at the apex of the gall bladder, from which several stones had passed into the peritoneal cavity. There also was a chain of fourteen large, densely calcified stones in the common bile duct. I think that that beautiful arc-shaped line of calcification across the film represents the chain of stones.

As is usual in a patient eighty-six years of age, there were many incidental lesions. She had generalized arteriosclerosis, contracted kidneys, a hyper-

trophied heart, calcification of the aortic valve with a slight grade of aortic stenosis and, of course, generalized peritonitis

Dr. SARRIS Was there any evidence of a previous fistula?

Dr. MALLORY The gall bladder was adherent to the transverse colon, but there was no fistula

CASE 33342

PRESENTATION OF CASE

A seventy-seven-year-old retired sea captain was admitted to the hospital because of dyspnea and orthopnea

Fifteen years prior to admission the patient had had pleurisy and had spent nine months in a sanatorium. He was then free from chest symptoms until nine months before admission, when he developed a "lump" below the right nipple that broke down, discharged a cupful of pus and remained open until the time of admission. Areas of the sinus tract were biopsied and showed acute and chronic inflammation, with granulation tissue and foreign-body, giant-cell reaction. Smears were negative for acid-fast organisms, but guinea-pig inoculations were not carried out. An x-ray film of the chest at that time showed extensive calcification at both apices, particularly on the right. There was no definite cavitation. Calcifications were also noted in both hilar regions. The diaphragm was flattened on the right and adherent laterally to a markedly thickened pleura, which extended upward for a distance of about 10 cm. The margin of the pleura was irregularly calcified. Four months before admission the patient noticed the onset of dyspnea and orthopnea, both of which became increasingly severe until the time of admission, when merely the effort of sitting up in bed caused dyspnea. Three months before admission a persistent cough, productive of small amounts of yellow sputum, appeared. Two weeks before admission the discharge from the sinus increased, but the cough seemed to decrease slightly. At the same time frequency, nocturia and burning on micturition, which had bothered the patient for about fifteen years, became much worse. During the two days prior to admission his general condition seemed much worse to his family, and a physician found the temperature to be 102°F.

Thirteen years before admission a transurethral prostatectomy had been performed because of the urinary symptoms mentioned above. These continued, however, and two years before admission, another transurethral resection was performed, with the diagnosis of fibrosis of the bladder neck. Four months before admission a biopsy of one of numerous small lesions on the face and forehead revealed a basal-cell carcinoma.

Physical examination showed a well developed but chronically ill man who was dyspneic on the

slightest exertion and somewhat disoriented. The skin showed a diffuse brownish discoloration. There were bilateral cataracts. The neck veins were distended. There were moist sticky rales throughout both lower-lung fields. There was edema and pigmentation of the ankles. The prostate gland was slightly enlarged, soft and tender.

The temperature was 101°F, the pulse 88, and the respirations 20. The blood pressure was 145 systolic, 85 diastolic.

Examination of the blood disclosed a red-cell count of 2,600,000, with a hemoglobin of 8 gm., and a white-cell count of 19,800, with 87 per cent neutrophils. The urine gave a ++ test for albumin, and the sediment contained innumerable white cells. Two sputum smears, three sputum concentrations, one gastric aspiration, one smear of material from the sinus tract and one concentration of the same material were negative for acid-fast bacilli. The total protein was 6.5 gm., the nonprotein nitrogen 44 mg. per 100 cc., and the chloride 116 milliequiv. per liter. Urine cultures grew out colonies of colon bacilli and pyocyanus bacilli, and those from the sinus tract, *Staphylococcus aureus* and a beta-hemolytic streptococcus. An x-ray film of the chest on the day of admission showed fluid in both pleural cavities and a granular increase in density throughout both lung fields, most prominent in the left midlung field.

During the hospital stay the temperature averaged 100°F, rising to 103° terminally, the pulse varied from 90 to 130, and the respirations from 20 to 40. Flatness and absent breath sounds developed at the right base, with bronchial breath sounds over the right middle lobe. On the eighth hospital day a chest film was described as not showing much change except a slight increase in the amount of fluid in the right side of the chest. The patient was given penicillin, sulfadiazine, fluids, Purodigin and oxygen and was put on constant bladder drainage. He did not do well, became gradually less responsive and died on the tenth hospital day.

DIFFERENTIAL DIAGNOSIS

Dr. J. GORDON SCANNELL In this case an acute and chronic pleuropulmonary infection had extended through the chest wall and failed to heal. There was also evidence of a chronic urinary-tract infection, which I consider chiefly incidental, and a degree of cardiac insufficiency consistent with the patient's age and debilitating illness.

The three most frequent causes of empyema necessitatis, followed by persistent fistula, are tuberculosis, actinomycosis and a neglected empyema due to one of the usual pyogenic organisms. Although pyogenic organisms were cultured from the sinus tract, the natural history of the lesion leads me to suspect that they were secondary invaders rather than primary agents. Also to be considered are the generic causes of persistent fistulas — namely, can-

cer, foreign body (including the sequestrum of osteomyelitis), syphilis and other mycotic and granulomatous infections. We have little specific bacteriologic evidence to support any of these, although it is conceivable that as a sea captain, assuming his command to be of reasonable size, the patient was exposed to all kinds of exotic infections. I mention the matter chiefly to point out that in many regions, although not in this area, pulmonary calcifications are said to be accompanied more frequently by histoplasmin than by tuberculin sensitivity, certainly, such calcifications are becoming less and less synonymous with old acid-fast infection.

Of the usual causes of persistent fistula of the chest wall, certainly tuberculosis must be ruled out. It seems entirely reasonable that the patient had had a tuberculous infection in the past, even if the organism could not be demonstrated during the present illness. Although the evidence is of negative nature and hence may well be proved inadequate, I am inclined to accept it at its face value and assume, therefore, that this was not tuberculosis. I am influenced chiefly by the failure to find tubercles in biopsies of the sinus tract, in addition to the convincing evidence of negative sputum concentrations and negative gastric lavage, either or both of which should have been positive if this had been an overwhelming tuberculous infection.

In the absence of acid-fast infection, the likeliest diagnosis is actinomycosis. Here again we lack positive bacteriologic evidence, but it is my experience that such evidence is frequently obtained with difficulty, especially in the face of secondary infection, until adequate pathological specimens are obtained.

Before proceeding further, I should like to review the x-ray films. To my mind the remarkable thing about the films taken four months before entry is the relative lack of demonstrable disease except for the process in the right lower portion of the chest. There is certainly evidence of old pleurisy on this side, with narrowing of the interspaces and apparent pleural thickening with calcification, but it seems to me that there also is parenchymal involvement of the right middle, as well as of the right lower, lobe. The films after entry and just before death seem consistent with acute bronchopulmonary infection and edema. The increase of the right pleural pocket, however, and the granular density in the left mid-lung field, are noteworthy and consistent with the productive type of inflammatory lesion consequent on actinomycosis.

DR MILFORD D SCHULZ. In the film taken six months before entry the most striking point is evidence of old pleurisy at the right base, with calcification. The entire right side of the chest is smaller than the left, which can be accounted for on the same basis. Evidence of an old acid-fast infection is not impressive.

The film made at the time of entry shows a granular mottling in the central portions of the lung which can certainly have been due to pulmonary edema. There is some fluid in the right pleural sinus, which, on a subsequent examination, is seen to have become pocketed low in the posterolateral portion of the chest like an encapsulated empyema. There may be chronic pulmonary disease in the right lower portion of the chest, but most of the irregular areas of density seem to be part of the pleural calcification.

A spot film of the right lower portion of the chest shows deformity of one rib. Perhaps the calcification in the pleura was due to hemorrhage following trauma.

DR SCANNELL. The x-ray films do not help us particularly in arriving at a specific diagnosis. They suggest, however, an explanation for the rather marked symptoms of pulmonary insufficiency—namely, the cumulative effects of old chest trauma, with crippling of the bellows mechanism and fairly extensive senile emphysema.

To return to the specific chest-wall infection, however, although the x-ray films certainly do not of themselves suggest actinomycosis, they are compatible with that diagnosis. Chiefly in favor of it is the apparent disregard the process had for anatomic barriers and the complete lack of any anatomically circumscribed lesion. Failure to recover the organisms in the discharge is the only barrier to a positive clinical diagnosis. A more complete description of the nature of the sinus tract would have been helpful, since an actinomycotic fistula usually presents a rather characteristic type of purplish, indolent granulations, and often an ant-hill type of fistula. The hint about yellow sputum is an encouraging bit of evidence, and the note about the reciprocal relation between cough and sinus suggests a bronchopleural-cutaneous fistula that did not assume major proportions.

I am aware that I am discarding a number of physical findings in devoting the major portion of the discussion to the chest, but I believe that in this age group the catalogue of incidental pathological findings will parallel the diversity of the therapy. The immediate cause of death, in my opinion, was failing respiratory and cardiac reserve in a man with a crippled respiratory apparatus and a reduced oxygen-carrying capacity.

I believe that the primary disease was actinomycosis of the pleura, lungs and thoracic wall, with secondary infection. As subordinate diagnoses I include pulmonary edema and chronic pyelonephritis.

DR LEWIS K DAHL. Despite the x-ray reports, which were read as being more consistent with pneumonitis or pulmonary edema than with tuberculosis, the clinicians who saw this patient believed that he had an overwhelming tuberculous infection, probably tuberculous pneumonia. No organisms

were found by smear, however, on several examinations of the sputum, gastric aspirations and sinus drainage. Death occurred, of course, before bacteriologic confirmation of this diagnosis could have been expected.

I saw the patient terminally and agreed with the numerous predecessors, I was disturbed that a thorough search for actinomycosis had not been carried out.

CLINICAL DIAGNOSES

Pulmonary infection, probably active tuberculosis
Sinus tract (? tuberculosis or from rib)
Bronchopneumonia
Benign prostatic hypertrophy
Urinary-tract infection

DR SCANNELL'S DIAGNOSES

Actinomycosis of pleura, lungs and thoracic wall
Pulmonary edema
Chronic pyelonephritis

ANATOMICAL DIAGNOSES

Organizing pneumonia
Chronic pneumonitis
Acute glomerulonephritis
Pulmonary edema and congestion

PATHOLOGICAL DISCUSSION

DR TRACY B. MALLORY. Dr Scannell has presented a persuasive case for actinomycosis. We naturally considered that diagnosis and did our best to substantiate it, but entirely without success. The right pleural cavity contained an old encapsulated empyema, and the left pleural cavity was entirely obliterated by fibrous adhesions. The lungs were

almost completely consolidated. The pleura over both lungs was thickened and fibrous, measuring up to 3 mm in places. At the left apex was an old puckered fibrous scar containing numerous small dilated bronchioles and much anthracotic pigment that was quite characteristic of a healed apical tuberculosis. There was no evidence of activity. The remainder of both upper lobes and about a third of each lower lobe were firm, noncrepitant and cut with difficulty, indicating diffuse fibrosis. The remaining lung tissue was markedly congested and edematous but still slightly crepitant. Microscopical examination showed all stages of organizing pneumonia from incipient lesions to dense fibrous scars. In many areas the persisting alveoli were partially epithelialized and contained many large phagocytes, filled with cholesterol vacuoles. Nothing suggestive of either tuberculosis or actinomycosis could be found.

The surprise of the autopsy was provided by the kidneys. Although not remarkable grossly, they showed on microscopical examination a severe grade of acute glomerulonephritis. It seemed probable, therefore, that renal insufficiency was an important factor in the immediate mechanism of death.

Little is known about the etiology of progressive organizing pneumonia. We have become increasingly aware of its importance in recent years. The clinical and x-ray pictures that it presents are readily confusable with pulmonary neoplasm, and consequently the surgeon is led to perform lobectomies or even pneumonectomies. In this case the presence of the acute glomerulonephritis suggests that the beta-hemolytic streptococci that were cultured during life were of more than coincidental importance. Whether they were the primary cause of the difficulty I cannot say from the evidence at hand.

Q FEVER IN THE UNITED STATES

ON PREVIOUS occasions mention has been made in these columns of the occurrence of Q fever and its relation to the nonbacterial pneumonias. The most recent reference¹ chiefly concerned a series of reports of circumscribed outbreaks of the disease that occurred in American and British military units in the Mediterranean area during the latter part of the war. Reference was made to outbreaks in this country that involved military units transferred from the Mediterranean Theater and laboratory workers engaged in the study of infectious material from the military units. In addition, a single case of Q fever acquired in Panama was mentioned.

It should be recalled that Q fever was first described as a severe influenza-like disease in Queensland, Australia, where it affected slaughterhouse workers, bushmen (foresters) and dairy workers.

The causative agent there was found to be a filter-passing agent that was called *Rickettsia burneti*, and the reservoir of infection was shown to be the bandicoot, a rodent that is prevalent in the Australian bush. Certain ticks serve as vectors to transmit infection to man either directly from these rodents or through domestic animals that serve as intermediate hosts. The feces of ticks were found to be heavily infected with the rickettsias.

In the United States a similar if not identical agent was found in ticks collected from several northwestern and southwestern states, all the way from Washington to Texas. Isolated cases of infection have been reported in this area, and an outbreak occurred in the laboratories of the National Institute of Health, where the agent was being studied. Interestingly enough, the workers in the particular laboratory where the agent was being investigated were not involved, and it was thought that the infection was air borne by means of infected dust. That outbreak was the first in which pulmonary lesions similar to those of primary atypical pneumonia were described. A second outbreak has occurred at the same laboratory.²

The first sizable outbreak of Q fever acquired naturally in the United States has now been described in considerable detail. This occurred among stockyard and slaughterhouse workers in Amarillo, Texas. The circumstances under which it took place are of considerable interest, suggesting that similar outbreaks may be expected where cattle from endemic areas are slaughtered.

The epidemiologic aspects of this outbreak are quite revealing.³ The cases all occurred among employees in a stockyard, its adjoining auction yards and a neighboring packing plant. There were 55 cases among 136 exposed persons. This is an attack rate of 40 per cent, which compares with the 50 per cent attack rates that were reported among the affected military units in the Mediterranean area. All the cases in this outbreak occurred between March 7 and 29, 1946, with 50 per cent of the cases in the stockyard workers beginning on or before March 10 and 50 per cent of those in the packing plant beginning on or before March 14.

A careful check of the sales' record revealed that only one lot of white-faced heifers, which were un-

loaded in the stockyard on February 23, could have fulfilled the requirement of having exposed all the categories of workers among whom the disease occurred. The known incubation period of the disease fitted perfectly: it was sixteen days from the day when this shipment was received to the day when 50 per cent of the cases began among the stockyard workers, and seventeen days had elapsed from the time when the slaughtering and processing of this lot of cattle began to the day when 50 per cent of the cases occurred in the packing plant employees. Among the latter, the attack rate among those engaged in killing the animals and in handling the freshly killed meat was 68 per cent, as compared with an 8 per cent attack rate among the remainder of the employees of the plant.

The actual mode of infection in this outbreak was not determined. No evidence was obtained to implicate an arthropod vector, and there was no evidence of person-to-person spread. Because of the explosive nature of the outbreak, and since evidence was obtained that afterward there were still a number of susceptible persons there, it was assumed that the infectious agent did not remain long in the packing plant. In the stockyard the epidemic lasted longer. The risk there involved all those handling live cattle, and although the first case among these employees occurred three days before the first case in the packing plant, the last occurred ten days after the outbreak in the packing company was over. It therefore appears that the infectious agent was present in the stockyards for a considerable period. It may have persisted in the dust, as suggested in the laboratory outbreak already mentioned, or it may have been deposited there from the excreta of cattle, since it is known to be present in the urine of experimentally infected animals and in the feces of the arthropod vectors. Another important feature of the outbreak is the fact that the disease was transmitted to stock handlers from apparently healthy cattle.

The clinical features of 18 cases that were studied were not unlike those described in the Mediterranean outbreak and among the infected laboratory workers.⁴ There was great similarity in the general symptoms, with wide variations in their severity. The outstanding findings were a rather abrupt onset

associated with frontal headache, chilly sensations, general malaise, high fever of five to ten days' duration, essentially normal white-cell counts, roentgenographic evidence of soft, diffuse, patchy infiltrative lesions similar to those of primary atypical pneumonia, with minimal symptoms and signs referable to the respiratory tract, and a rapid and uneventful convalescence. There were practically no cutaneous lesions, the spleen was felt in only one case, and the lymph nodes were not enlarged.

Serologic tests were relied on to establish the diagnosis in almost every case.⁵ Significant titers of complement-fixing antibodies were demonstrated with Q fever antigens during the second week after the onset of illness, in some cases, however, the highest titers were not reached before the fourth or fifth week. In most cases, high titers were maintained at least for a few weeks. Positive serologic confirmation was obtained in 49 of the 55 suspected cases. The complement-fixation tests were highly specific for Q fever, the same serums failing to show rises with endemic typhus or spotted-fever rickettsial antigens. Serums from unexposed persons, including household contacts of the cases, gave negative results. Some positive serologic results were obtained in a small group of presumably exposed persons, suggesting that there may have been unrecognized illness or inapparent infection.

Strains of rickettsia apparently identical with *Rickettsia burneti* were isolated from the serums of 2 cases.⁶ This was accomplished by workers in the virus and rickettsia division of the Lederle Laboratories. Although guinea pigs have generally been used for isolating the agent from human blood, the strains from this outbreak were obtained by passage through dilute brown agouti (dba) mice, which have already been found to be of value in studies of other viral and rickettsial diseases.

It is to be expected that Q fever will again be encountered in this country, and the experience in Australia suggests that the occurrence of this disease among persons who handle cattle that originate in endemic foci may be anticipated. Indeed, an outbreak of Q fever is alleged to have occurred recently in one of the Chicago packing plants, but details of this outbreak have not yet

been published. It may be difficult to detect the presence of infection in animals except by careful epidemiologic and serologic studies. It seems worth while, however, to make a survey among herds of cattle in an attempt to discover the various foci of this infection and to determine its mode of transmission in this country, with a view toward the development of methods for its control.

A report of a case of Q fever that was diagnosed in Boston but was acquired in Italy appears elsewhere in this issue of the *Journal*. This case emphasizes the importance of considering Q fever in the differential diagnosis of nonbacterial pneumonias in areas where the agent is known to occur and in persons who have been in such areas within the incubation period of the disease. Since the foci and reservoirs of infection of Q fever are not all known it is well to be on the alert for the occurrence of the disease in new localities. It should also be borne in mind that Q fever may manifest itself, as it usually does in Australia and perhaps in the Balkans, as a rather severe influenza-like infection with a more prolonged febrile course than that usually seen in influenza-virus infections but without evidence of pulmonary involvement.

NEW ARMY MEDICAL CENTER

THE Office of the Surgeon General has released plans for the construction, by the Army Corps of Engineers, of the greatest medical research center in the world. This group of buildings, to be erected at Forest Glen, Maryland, at an initial cost of approximately \$40,000,000 will be equipped to anticipate and meet the medical problems of the future as well as to cope with those of the present—certainly a worthy and certainly an ambitious program.

The official designation of this imposing project is the Army Medical Research and Graduate Teaching Center. It will consist of a 1000-bed general hospital capable of expansion to 1500 beds, an administration building housing also the Army Medical Museum, a building for the Army Institute of Pathology, buildings constituting the Central Laboratory Group, a working library, staff quarters, an animal farm and other buildings.

The location at Forest Glen, just outside Washington, D. C., will provide a close relation to the Walter Reed General Hospital, the Navy Medical Center, the medical schools of Washington and the proposed Washington Medical Center. The Center will also have the advantage of co-operation with the National Bureau of Standards, the National Institute of Health and the National Research Council. Two hundred of its beds are to be specifically designated for research.

The Institute of Pathology will house the Department of Pathology, the American Registry of Pathology and the Army Medical Illustration Service. The Institute of Medicine and Surgery will house the departments of Research Medicine, Research Surgery, Research Dentistry, Veterinary Medicine, X-ray and Radiation, and Preventive Medicine. There will thus be brought together units from all over the country: the Medical Nutrition Laboratory from Chicago, the Medical Field Research Laboratory from Fort Knox, Kentucky, and the Surgical Research Unit from Fort Sam Houston, Texas.

Centralization is the keynote today, the medical centers that have sprung up and are springing up or would like to spring up are legion. Centralization, moreover, has tremendous advantages with its pooling of equipment and of administrative facilities and its opportunities for the exchange of ideas. It also has its disadvantages: a rigidity where flexibility is desirable and the stifling of individual enterprise, the Army never having been noted for its eager reception of new ideas. But such a splendidly conceived institution offers a great opportunity, and it is to be hoped that the Army will use this opportunity to its fullest advantage, without the traditional Army wastefulness of men and materials.

Stone walls do not a prison make, but neither do marble halls inspire original thinking unless freedom of thought and devotion to the truth are in the very mortar that binds their blocks together. Open minds as well as dollars must be put into the Army Medical Center. Originality seems to avoid conventional surroundings: radium came to us from a dilapidated shed in Paris, Sir Isaac Newton received the full impact of his epoch making apple while sitting under a tree, and Mr. Baruch is known to have given forth some of his most valuable ideas while sitting on a park bench in Washington.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

BAXTER—G. Raymond Baxter, M.D. of Newton Center, died on July 24. He was in his fifty-third year.

Dr. Baxter received his degree from Tufts College Medical School in 1922. He was a fellow of the American Medical Association.

His widow survives.

BLAIR—Orren C. Blair, M.D. of Lynn died on August 3. He was in his sixty-seventh year.

Dr. Blair received his degree from Harvard Medical School in 1903. He served on the surgical staff of the Lynn Hospital and was a fellow of the American College of Surgeons and the American Medical Association.

His widow, a son and a daughter survive.

GILMAN—Florence Gilman, M.D. of Northampton died on August 1. She was in her seventieth year.

Dr. Gilman received her degree from Tufts College Medical School in 1903. She was formerly physician at Radcliffe and Smith colleges and assistant physician at Vassar College and was a fellow of the American Medical Association.

A niece survives.

GOODALL—Edwin B. Goodall, M.D. of Newton Center died on August 6. He was in his sixty-sixth year.

Dr. Goodall received his degree from University of Maryland School of Medicine and College of Physicians and Surgeons in 1909. He was a member of the New England Ophthalmological Society and the American Academy of Ophthalmology and Oto-Laryngology.

His widow survives.

NIGHTINGALE—James Nightingale, M.D., of Worcester, died recently. He was in his seventy-second year.

Dr. Nightingale received his degree from Harvard Medical School in 1900. He was formerly medical director of the Jewish Home for Aged and Orphans and was a fellow of the American Medical Association.

An aunt and two nephews survive.

ROY—Joseph N. Roy, M.D., of Webster died on March 19. He was in his seventy-fifth year.

Dr. Roy received his degree from Baltimore University School of Medicine in 1902. He was a fellow of the American Medical Association and an organizer of the Webster District Hospital.

His widow, a son and two daughters survive.

WENTWORTH—Arthur H. Wentworth, M.D., of Falmouth, died on July 30. He was in his eighty-fifth year.

Dr. Wentworth received his degree from Harvard Medical School in 1891. He was a former member of the Massachusetts Medical Society.

A daughter and seven grandchildren survive.

MEDICOLEGAL ABSTRACT

Hospitals Applicability of the Massachusetts Labor Relations Act and the Federal Labor Management Relations Act. As a result of the decision of the Massachusetts court in *Saint Luke's Hospital v. Labor Relations Commission*, decided on November 30, 1946, and of the Labor Management Relations Act, enacted in 1947 by Congress over President Truman's veto, charitable hospitals in Massachusetts are in general exempt from the provisions of the state and federal labor-relations acts. The new Labor Management Relations Act by its definitions has excluded "any corporation or association operating a hospital if no part of the net earnings inures to the benefit of any private shareholder or individual." The Massachusetts Labor Relations Act contains no such provision, but the same result is accomplished by the decision of the Massachusetts court in the *Saint Luke's Hospital* case.

In that case the Laundry Workers, Dry Cleaners and Miscellaneous Workers of the Amalgamated Clothing Workers of America had sought certification by the Labor Relations Commission as the collective bargaining agency of certain nonprofessional employees of the hospital. The hospital sought the ruling of the courts whether or not the Massachusetts Labor Relations Act, on which the union was relying, applied to the hospital. The court held that the hospital was a public charity and not engaged in industry and trade and that therefore the act did not apply because it applied only to questions affecting industry or trade. The court declined to consider whether this same decision would be made if a hospital "were engaged in commercial undertakings, as the care and letting of realty or the conduct of a mercantile establishment, for the benefit of the hospital and employed persons in such undertakings."

Charitable hospitals should not infer from the decision or from their exemption under the new federal Labor Management Relations Act that it is illegal for their employees to join labor unions or even that the hospitals have an entirely free hand to take whatever steps they may see fit to attempt to prevent the unionization of their employees. For, although the rights and privileges that the state and national labor-relations acts give to employees generally do not now extend in Massachusetts to the employees of charitable hospitals, employers in Massachusetts were subject to some restraints in resisting the unionization of their employees even before those acts were passed.

MISCELLANY

RHEUMATIC FEVER RESEARCH

An announcement was made on July 7 of the formation of the Helen Hay Whitney Foundation for basic scientific research in rheumatic fever. The members of the distributing committee of the Foundation are Mrs. Charles S. Payson

(Joan Whitney), John Hay Whitney, Frederick K. Trask, Jr., and William Harding Jackson. Dr. T. Duckett Jones, of Boston, has been appointed medical director of the Foundation, with temporary offices in the New York Hospital, 525 East 68th Street, New York City. Dr. Jones, who has been granted a leave-of-absence from his positions at the Harvard Medical School and the House of the Good Samaritan, stated, "The purpose of the Foundation is to make possible research that may increase our knowledge of rheumatic fever—the leading fatal childhood disease."

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

The Unconquered Plague. A popular story of gonorrhea. By Harry Wain, M.D., M.S.P.H. 12°, paper, 119 pp. New York: International Universities Press, 1947. \$1.50.

This small book, written for the laity, treats of the medical and social aspects of the disease. In order are considered the disease and its history, the gonococcus, its effects on men, women and children, its treatment and prophylaxis and gonorrhea is a social problem. The chapter on prostitution and sexual promiscuity could have been omitted without lessening the value of the book. A glossary and index complete the volume. The price is excessive.

Pediatric Gynecology. By Goodrich C. Schauffler, M.D., assistant professor of obstetrics and gynecology, University of Oregon Medical School, and visiting gynecologic surgeon and obstetrician, Multnomah Hospital, Portland, Oregon. Second edition. 8°, cloth, 380 pp., with 75 illustrations. Chicago: Year Book Publishers, Incorporated, 1947. \$6.00.

This second edition of a work first published in 1942 has been thoroughly revised to bring it up to date, and new material has been added in nearly every chapter. The section on gynecologic surgery in children has been expanded, and those on social service and medicolegal aspects have been considerably revised. Data on the use of penicillin have been incorporated throughout the text. The lists of commercial preparations of sex hormones and of state welfare agencies have been brought up to date. The sex problems of children, including masturbation, are discussed in the chapter on the external genitalia. The volume is well published in every way and should be in all medical libraries and in the libraries of gynecologists and pediatricians.

NOTICES

ANNOUNCEMENT

Dr. Benedict F. Massell announces the removal of his office to the House of the Good Samaritan, 25 Binney Street, Boston 15.

SUFFOLK CENSORS' MEETING

The censors of the Suffolk District Medical Society will meet for the examination of candidates at the Boston Medical Library, 8 Fenway, on Thursday, December 4, at 4:00 p.m.

NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children will be held on Thursday, September 4, at 7:15 p.m., in the classroom of the Nurses' Residence. The subject "Sympathetic-Nervous-System Drugs, Old and New" will be discussed. Dr. Esther E. Bartlett will be chairman.

GRANTS AND FELLOWSHIPS IN CANCER RESEARCH

The Committee on Growth of the National Research Council, acting for the American Cancer Society, is entertaining applications for grants and fellowships. Applications for extension of existing grants in cancer research will be received until October 1, and applications for new grants until November 1. Applications for fellowships and senior fellowships in cancer research may be submitted until December 1.

Final decision on applications submitted during this period will be made in most cases soon after February 1. The grants ordinarily will become effective on July 1, 1948. Fellowships may begin at any time determined by the committee, although ordinarily these also will take effect on July 1.

During the last two years the American Cancer Society, acting on the recommendation of the Committee on Growth, has awarded one hundred and seventy-six grants and forty-seven fellowships, representing a total expenditure of some \$2,700,000. The committee will continue to recommend support of biologic and clinical research dealing broadly with phenomena relating to growth, typical or neoplastic. In the formulation of this program the committee will be guided, as in the past, by the advice of some one hundred and twenty scientists grouped in twenty panels, comprising its sections on Biology, Chemistry, Physics, Chemotherapy, Clinical Investigation and Fellowships.

Communications regarding grants or fellowships should be addressed to the Executive Secretary, Committee on Growth, National Research Council, 2101 Constitution Avenue, N.W., Washington 25, D.C.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, AUGUST 28

WEDNESDAY, September 3

*12:00 m. Grand Rounds and Clinicopathological Conference (Children's Hospital) Amphitheater, Peter Bent Brigham Hospital.

*Open to the medical profession.

SEPTEMBER 2-6 American Congress of Physical Medicine Page 610, issue of April 17.

TRAUMATIC ARTERIAL VASOSPASM

PHILIP S FOISIE, M.D.*

BOSTON

THE opportunity of treating a large number of war wounds of the extremities has demonstrated that vasospasm, of varying intensity and obstinacy, often complicates these injuries. This paper is not primarily concerned with cases of subtotal ischemia in which the immediate viability of the part is threatened but with the less dramatic and much larger group in which the persistence of a relatively low-grade arterial spasm is likely to cause nutritional changes adversely affecting the functional result.

Everyone is alarmed when a wound involves or suggests injury to a major artery, modern surgeons are equally apprehensive about the cold, pulseless limb produced by a widespread and intense arterial spasm, of which there have been many reports in recent years. Too little concern, however, is generally shown about the more moderate picture of arterial spasm, which holds little or no threat to the viability of the limb but a serious one to the ultimate function. In my opinion some of these unsatisfactory functional results are not entirely unavoidable. They have been explained by diagnoses of traumatic arthritis, Sudek's atrophy, neurotrophic edema and other titles to fit the prominence of certain signs found in the so-called "causal states," and thus the surgeon has considered himself absolved of responsibility for the functional result. An impaired arterial blood supply due to a subacute arterial spasm is regarded as the fundamental cause of much disability not inherent in the original injury. Recognition of the ischemia and rational specific therapy are essential to proper treatment.

INCIDENCE AND PREDISPOSING FACTORS

Although actual percentage figures of the occurrence of vasospasm in war injuries are not available, the clinical experience of one particularly interested in this phenomenon is not without value. In a hospital averaging 1500 war casualties, of which about 85 per cent were surgical, and excluding cases of trench foot (all of which presented some degree of

vasospasm at one stage of the disease), an average of 12 to 15 cases were constantly being watched and treated for vasospasm that was considered sufficiently pronounced to endanger the functional result.

From this experience, can any conclusion be reached regarding what sort of injury is likely to be complicated by arterial spasm? Are the increased wartime incidence and interest in this and allied disorders due to anything peculiar to battle casualties, and what application is there to civil practice? These questions are considered under the following headings: the extent and location of the initial injury, the tissues involved, individual susceptibility, and blast effect.

Extent and Location of Original Injury

Contrary to what might be expected, the incidence of arterial spasm does not parallel the severity of the original wound. Patients with extensive wounds involving shattering compound fractures, with much soft-tissue destruction of the upper portion of an extremity, may have quite adequate circulation in the distal portion of the same limb, whereas minor injuries to toes or fingers may set up a vasospasm so severe as to threaten function. Wounds were often seen with such extensive loss of substance as to make one wonder how sufficient circulation could get through to the distal portion, and yet the circulation there was found to be adequate. In 1 case, in spite of extensive loss of substance in a wound of the elbow, no clinical evidence of vasospasm appeared, and the circulation to the distal portion of the extremity remained adequate (Fig 1).

In another case a shell fragment tore through the upper extremity, taking with it the greater portion of the humerus (Fig 2). In spite of the soft-tissue destruction obviously involved, the circulation to the forearm and hand remained adequate. It should be noted that in these extensive injuries the wound is wide open—thoroughly decompressed. This factor is discussed below.

*Instructor in surgery, Tufts College Medical School, assistant surgeon, Fourth Surgical Service, Boston City Hospital, formerly chief of surgery, 15th General Hospital, United States Army.

Conversely, some of the most stubborn cases of vasospasm complicated mild injuries. A patient whose only injury was a bullet wound through the proximal phalanx of the left little finger that healed promptly, but with some deformity and a tender scar, developed such persistent vasospasm that dorsal ganglionectomy was required after all other

teries have a natural tendency to contract to prevent excessive blood loss and that vasospasm is produced by the sympathetic system. It is logical, therefore, to look for direct trauma to large arteries or nerves in attempting to analyze the cause of vasospasm. Many reported cases with direct trauma, particularly to large arteries, have been complicated by extensive spasm. This is not, however, an essential part of the mechanism, and in the cases presented below, there was often no evidence of direct injury to main arteries or nerves. Illustrative of this are the 2 cases in which the injuries were confined to digits, with no possibility of direct trauma to important arteries or nerves but which presented stubborn vasospasm. In other cases, although the site of the wounds did

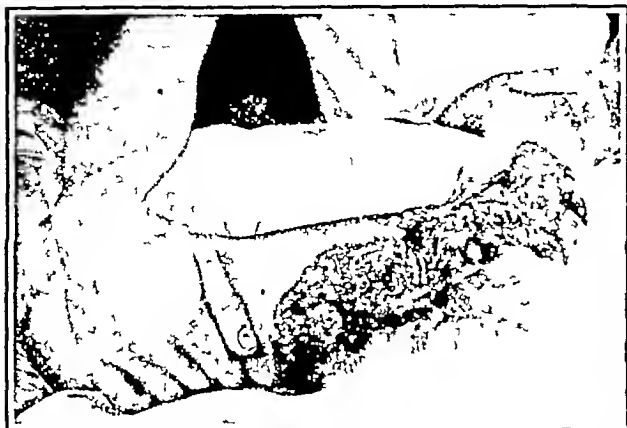

FIGURE 1 *Photograph of a Shell-Fragment Wound of the Right Arm*

Despite extensive soft-tissue injury, circulation remained adequate

efforts to restore circulation had failed. After this operation good circulation was restored, and the patient regained full function of the hand and fingers. This case is reported in detail below. Another patient was injured by a small shell fragment, which passed between the first and second toes of the left foot, causing mild wounds to the adjacent sides of the two digits. A week later the wounds were healed, but the foot was cold and cyanotic. So obstinate was the vasospasm that after all measures for vasodilatation, including repeated sympathetic blocks, had given only temporary relief, lumbar ganglionectomy was done two and a half months after injury, and the arterial supply subsequently remained adequate.

My experience is that the incidence of vasospasm does not rise with the severity of the wound but is found oftener in the smaller, quickly closed wounds than in the larger, wide-open ones. This suggests that tension is a factor and may explain the fact that a certain measure of success attended the decompression of early Volkmann's contracture by multiple, long incisions in the period when that complication was attributed to venous congestion. Although I am convinced that the proximate mechanism of Volkmann's contracture is an intense arterial spasm,¹ increased tissue tension may be a factor in the spasm.

Tissues Involved

Most people associate arterial spasm with injury to arteries or nerves. It is known that injured ar-

FIGURE 2 *Roentgenogram of a Shell-Fragment Wound of the Shoulder and Arm*

Despite extensive loss of tissue, including the greater part of the humerus, circulation to the forearm remained adequate

not offer such absolute preclusion of artery or nerve injury, evidence in favor of such injury was not usually found. Wounds from flying shell fragments followed no pattern and were seen in all locations, courses and degrees of severity—the impression that such factors influenced the incidence of vasospasm was not gained.

Individual Susceptibility

In an analysis of this sort, a predisposition of the patient must be considered at least briefly. There is

something to be said for such a possibility. Some people, even in the best of health, often suffer from cold extremities due to vasomotor lability. If to this is added the rigors of battlefront conditions before injury—physical and nervous exhaustion, deficiencies of diet and body hygiene and all grades of exposure to the elements—some element of predisposition cannot be denied.

Blast Effect

So far, rather negative conclusions have been reached, but one factor that may for the moment be called the "blast effect" is, in my opinion, positive. An appreciable number of self-inflicted wounds were treated. In these cases the first and second toes of the left foot were most frequently injured. Occasionally, a more determined or a less careful patient had blasted through the metatarsal region. Since these patients were usually in no particular hurry to be rehabilitated, their slow progress was at first attributed to lack of co-operation in active exercises. It was soon realized that in this type of wound the incidence of vasospasm was high—in fact, to some degree at least, almost universal.

In such close-range wounds the blast effect or concussion was obviously severe, with diffuse intracellular damage. Vasospasm has been noted in the so-called "crush syndrome" (Bywaters²). In fact, in a case in which the leg had been crushed in an air raid, vasospasm of the opposite, uninjured leg resulted in the loss of two toes.³ This mechanism may be operative to some extent in so-called "winger injury."

On the basis of the high incidence of vasospasm in cases in which the blast factor is heavy, it can perhaps be understood why war injuries, which are largely caused by ragged, irregular shell fragments propelled by high-explosive forces, are more frequently complicated by vasospasm than civil accidents. In 1935 Montgomery and Ireland⁴ published a review of the literature in which they reported 44 cases of "traumatic segmentary arterial spasm" resulting from all kinds of trauma, of which 26 were the result of gunshot or high-explosive injuries. The comparatively smaller penetrating or perforating wounds probably cause more blast effect, at least on the remaining tissue, than the larger evulsing wounds, which are also decompressing.

In my experience the incidence of vasospasm is not dependent on the extent or location of the injury, or particularly on the structures involved, it is higher in the less open wounds, some predisposition may be operative, and diffuse tissue damage due to the concussive effect of explosive missiles is a factor.

CLINICAL PICTURE

In traumatized extremities vasospasm has been found in all degrees of intensity and distribution. This paper is concerned particularly with the less

severe grades that might escape the unobservant. An example of arterial spasm in its simplest form occurred in a soldier who had suffered a rather minor soft-tissue wound over the proximal portion of the dorsum of the right foot that had nearly healed. Inspection of the foot revealed a striking and most unusual color change. The medial half of the dorsum of the foot, including the first and second toes, was blanched to a dead white, in contrast with the normal pink of the lateral half and the fourth and fifth toes—the third toe showed partial

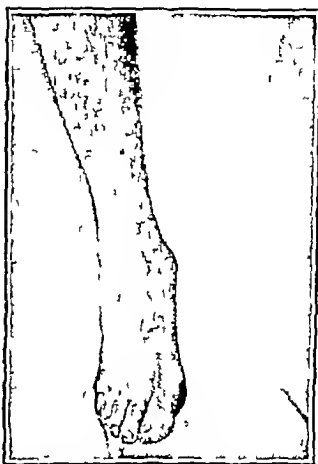

FIGURE 3 Photograph Illustrating Vasospastic Ischemia Secondary to a Penetrating Wound of the Calf. The three white areas are finger pressure spots. Note the irregular blanching particularly in the distal portion of the foot.

changes. On palpation the blanched area was cold, and the pink area was warm, tactile sensation was less acute in the affected portion. The extremity constituted almost an arteriogram of occlusion of the dorsalis pedis artery—substantiated by an absent pulse in that vessel. The ward officer and the patient had noticed the condition for at least two or three days but had not been aware of any difficulty before that time. Treatment of any sort was postponed so that pictures could be made to record such a precisely demarcated example of arterial block, but they were never made. The next morning the foot was quite normal, and no recurrence took place—it was not possible to stimulate one even for the record. There was no intrinsic damage to the dorsalis pedis artery, which had been caught in a segmentary reflex spasm stimulated by some impulse from the nearby injury. Although most complete and sharply defined while in effect, it was

transient, and its spontaneous disappearance was equally complete. This case is not regarded as involving any threat to the ultimate function of this particular foot but rather as a classic example of arterial spasm in its simplest form. It is the element of which the more extensive and more obstinate syndromes are composed. The prominent features of such a picture are of interest.

Color change is the outstanding sign. It varies under different conditions but always differs from that in the opposite member. At room temperature and at rest the color is a combination of pallor and cyanosis (Fig 3). The pallor is usually spotty,

An interesting group of symptoms is that based on the common denominator of local discomfort. Unlike the complaints in the true causalgias, severe pain is rare, although moderate degrees of pain may occur. The patient often complains of numbness, coldness, tingling or other such descriptive paresthesias but is reasonably comfortable so long as the extremity is supported and at rest. There is local tenderness, out of proportion, it may seem, to the force of palpation — indeed, even the threat of palpation is poorly received. The patient's guard is always up — a picket line that ward attendants and fellow patients soon learn not to cross. The ex-

FIGURE 4 Roentgenograms of Both Feet of a Patient with a Compound Fracture of Both Bones of the Right Lower Leg

This patient had signs of vasospastic ischemia when seen five months after injury. Note the osteoporosis in the bones of the right foot (right).

whereas the cyanosis is diffuse, increasing distally in depth. As compared to the opposite side the lack of red tones is distinctive. With dependency or exposure to cold, particularly on wet days out of doors, the cyanosis increases, and with elevation it fades and pallor increases. The extremity actually looks cold.

The surface temperature is obviously decreased, being lowest distally. Sometimes the patient volunteers this as a subjective complaint. The lower surface temperature is easily noticed by a comparison of palpation with that on the other side or the proximal part of the same extremity. All grades from a barely perceptible difference to a definite chill have been observed. Almost a part of the cool sensation is that of dampness — a combination sufficiently unpleasant to arrest attention and interest.

Swelling is generally seen in all injuries, particularly on use and dependency after plaster immobilization. Cases presenting ischemia are no exception. Anoxemia increases permeability of the capillary walls and increases interstitial fluid. The amount of fluid thus caused, however, is not large, and unless other factors contribute, edema is moderate.

the extremity is held immobile, with the joints flexed. There is a disinclination to exercise and a disapproval of any manipulation. This symptom complex in itself retards rehabilitation and may make one suspect the patient of poor co-operation.

Finally, the most specific, reliable and convincing sign of arterial spasm is the finding of diminished or absent peripheral pulses, complemented by adequate pulses on the alternate side and variably responsive to measures of vasodilatation. The parallel between the observable evidence of ischemia and the lowered pulse volume is reasonably consistent.

VASOSPASM AS A SPECIFIC ENTITY

Of course, vasospasm is not accountable for all circulatory deficiencies following injury. Swelling and cyanosis are usual after fractures, particularly during the initial mobilization period. Impaired venous return and the softening of disuse and lowered local metabolism must be overcome in all injuries of any moment. Beyond this, however, the careful observer will find that in some cases a definite deficiency exists on the arterial side, the swelling is less prominent, the cyanosis contains more pallor and less redness, the surface temperature is lower,

there is more discomfort, and the distal pulse is diminished or absent. Although arterial spasm probably occurs oftener in war wounds it seems to complicate certain civil injuries more frequently than may have been suspected. All grades of severity and of extension are possible, and the development can be insidious. Arteriospasm has probably been overlooked at times, or its results attributed to other causes.

Blackwood³ presents the following description:

The arteries are the supply lines. An ischemic limb resembles the inhabitants of a beleaguered town. With

blood supply is of primary importance for repair of injury and for maintaining good tone of the extremity pending return of function. Arterial spasm complicating injury throttles a blood supply that needs to be at its best.

THERAPY

So far as possible, cases presenting vasospastic ischemia were grouped together. It was believed that both the patients and the ward personnel could more easily be indoctrinated in the general program and the results better evaluated. Basically, blood

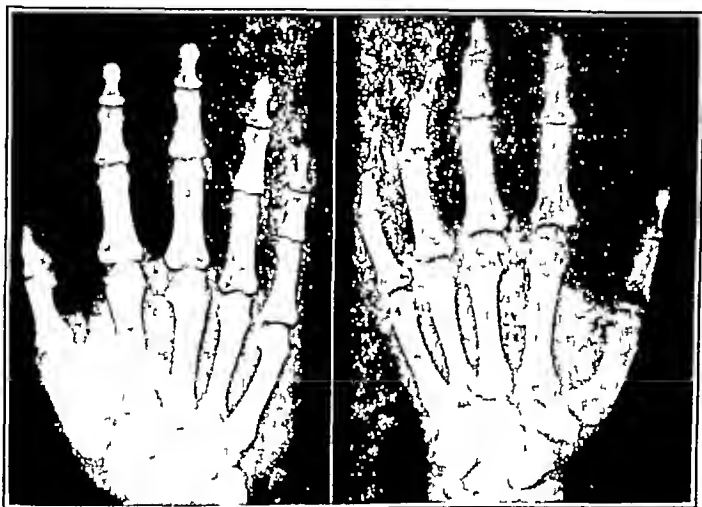

FIGURE 5 Roentgenograms of Both Hands Taken Three Months after the Patient Sustained a Shell Fragment Wound of the Upper Right Arm, with No Fracture or Nerve Injury

The hand was still cold and blue. Note the decalcification, the haziness of joints, the atrophy of the soft parts, and the flexion of fingers of the right hand (right) as compared with those of the normal hand (left).

supplies diminished or cut off they can keep up normal appearances for a time, but soon they begin to starve. They feel cold, their faces are pale or blue, they become less active and as conditions grow worse they become apathetic, or complain loudly to those in authority. In the human limb there is absence of arterial pulsations, lowering of surface temperature, pallor or cyanosis, an anesthesias and pain.

As stated above, this report is not primarily concerned with the limbs whose lines have been completely cut off but rather with those that are on short rations. Malnutrition, which is the basic difficulty, results in degenerative changes of the musculoskeletal system primarily. Muscle atrophy, osteoporosis, limited and painful motion, flexion deformities and joint stiffness are the price of a prolonged arterial inadequacy (Fig. 4 and 5). A rich

loss and dehydration were corrected, and adequate diet, added vitamins and sufficient rest assured. Some patients received 4 gm. of aspirin a day and 30 cc. of whisky three times a day, but no improvement was noted from this medication. Buerger's exercises were used routinely, without relief of the arterial spasm. The extremities were kept warm but not overheated (these patients were not allowed beds near the stoves), and exposure to cold and inclement weather was avoided. Heaters to other parts of the body were used, and warm (not hot) soaks were given to the affected parts several times a day.

Paravertebral novocain blocks, which were employed as soon as the condition was observed, al-

most universally caused improvement for at least a short time—even if only for a couple of hours. More frequently, such improvement lasted for two or three days. Blocks were repeated several times if necessary and so long as improvement increased

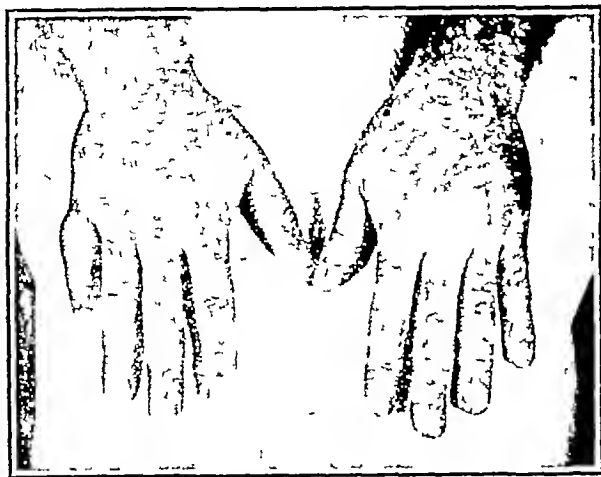

FIGURE 6 Photograph of Both Hands of a Patient Presenting Vasospastic Ischemia (Case 1)

Note the moderate swelling and cyanosis of the right hand, which was also cool

with successive blocks. If the interval of improvement decreased progressively, ganglionectomy was considered. This operation was done in 4 cases in which vasospasm persisted beyond all the treatment

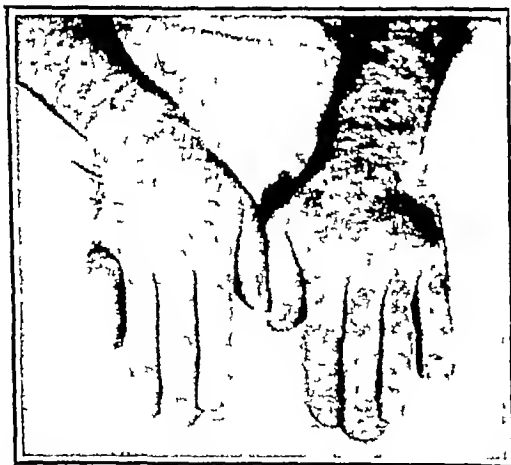

FIGURE 7 Photograph of the Same Hands after Right Upper Dorsal Ganglionectomy

The cyanosis and swelling have disappeared. After initial marked vasodilatation, the hand took on a normal color

mentioned above, and in each case permanent relief of symptoms resulted

CASE REPORTS

The following cases of persistent low-grade vasospasm illustrate the difficulties sometimes encountered

CASE 1 J C, a private first class, while in close fighting in France on June 14, 1944, sustained a bullet wound of the right fifth finger and was struck on the forehead by the stock of an enemy rifle. He was not unconscious. On the same day he was admitted to a field hospital, where the finger wound was débrided. He was evacuated by air to England, arriving at a general hospital on June 17. At that time a lacerated wound in the center of the forehead was found, x-ray examination of the skull was negative. A perforating rifle wound, whose entrance was on the dorsum of the proximal phalanx of the right fifth finger and whose exit was on the palmar aspect of the same phalanx, was also observed with a compound, comminuted fracture of the proximal phalanx.

The wound was dressed with vaseline-soaked gauze, and a splint was applied. By July 11 the wounds had healed, and the fracture had united solidly, the finger was stiff, tender

FIGURE 8 Photograph of Both Feet of a Patient with Shell Fragment Wounds of the First and Second Toes of the Right Foot, Complicated by Obstinate Vasospastic Ischemia (Case 2). Note the moderate swelling, as well as the diffuse cyanosis contrasting with the finger-point blanching

and painful, however. The patient was sent to the physiotherapy section, where he received daily whirlpool-bath treatments and exercises for 2 weeks. On August 4 he was transferred to the rehabilitation group, where for 1 month he took part in the program but complained of pain and tenderness in the finger and that the whole hand became blue and cold, particularly when he was outdoors. Because of these complaints he was given further physiotherapy, with no improvement, and was returned to the hospital on September 4. Examination disclosed general pallor of the hand, with cyanosis (Fig 6). The radial pulse was palpable, but the ulnar pulse was not. A stellate ganglion block with novocain was done on September 6. This resulted in a warm, pink hand with palpable pulses that lasted for 3 days. Owing to a novocain reaction the block was not repeated, and on September 11 the finger scar was revised and a spicule of bone was removed in the hope of relieving pain. At the same time the ulnar artery was stripped just above the wrist. Good pulsations, surface color and temperature followed this

procedure, but after 1 week the signs and symptoms of local ischemia returned. By that time even the uninjured fingers had limited motion and the functional result was poor.

On September 28 an upper dorsal ganglionectomy was done through a posterior incision the second and third thoracic segments being removed. This resulted in a warm pink hand with good pulses (Fig. 7), and no further evidence of ischemia. Function of the hand was completely restored except for permanent stiffness of the proximal joint of the little finger.

CASE 2. W. S., a 31 year-old private, was wounded in action in France on July 7, 1944 by fragments from an 88-mm. shell. He sustained wounds of the right upper arm both buttocks and the first two toes of the right foot. On the same day the wounds were debrided and a metallic foreign body was removed from the second toe under Pentothal anesthesia at an evacuation hospital.

On July 13 the patient arrived at a general hospital in England where examination revealed a moderate penetrating wound on the posterior aspect of the right upper arm, moderate lacerating wounds of both buttocks, moderate penetrating wounds on the medial aspect of the right great toe and the lateral aspect of the right second toe, compound comminuted fractures of the middle and distal phalanges of the right first toe and middle phalanx of the second toe, and a metallic foreign body in the middle phalanx of the right second toe.

The wounds healed promptly without surgical closure. The patient was urged to get about but complained that pain in the great toe prevented his becoming ambulatory. On August 15 the ward surgeon insisted that he attempt to walk. When he did so the foot became swollen, cyanotic and cold. He complained of pain throughout the whole foot, particularly over the scar on the great toe. The dorsalis pedis pulse was palpable but weaker than that of the opposite foot. A course of physiotherapy was ordered with no improvement in 2 weeks. On September 1 a plastic repair was done on the scar of the first toe, and the foreign body was removed from the second toe. The scar subsequently gave no further pain, but the foot remained cold and cyanotic and he complained of pain through the foot (Fig. 8).

On September 13 a lumbar ganglion block was done with good immediate results. The color and surface temperature improved, and there was subjective relief that lasted for 4 days. On September 20 a second lumbar block afforded similar relief but for only for 1 day.

On September 28 a lumbar ganglionectomy was done, with sustained relief. Thereafter the foot remained warm, pink and painless. There was some swelling when the patient became ambulatory, but this subsided with use and the patient was walking well and without complaint when he was discharged from the hospital on November 2 (Fig. 9).

These cases, which are extreme rather than representative, are reported to illustrate the full range of therapy, of which lesser measures usually suffice. In most cases careful attention to supportive routine, in addition to several sympathetic blocks, restored adequate circulation. Often, a single novocain block brought about improvement that could be maintained by careful attention to the supportive measures mentioned above. The amount of treatment indicated depends entirely on the stubbornness of the vasospasm, which can be measured only by its response to therapy.

CIRCULATION

In a discussion of the treatment of vasospasm some consideration should be given to the objections to sympathetic paralysis recently presented by Cohen^{6,7} and supported by the experiments of Friedländer et al.⁸ Cohen points out that the circulation of the deep structures, particularly the muscle bellies, is independently regulated as compared with that of the surface structures, because

their needs for increased blood supply do not coincide. He concludes that an extremity with a blanched, cool surface represents a protective mechanism, the available blood being shunted to the deep structures, which are more vulnerable to its loss. He believes that sympathetic paralysis, under these conditions, diverts blood to the surface

FIGURE 9 Photograph of the Same Feet after Right Lumbar Ganglionectomy

Note the improvement in color and the absence of swelling

at the expense of the deep circulation and thus prevents the anticipated result.

These arguments, besides being of considerable interest, are of more than academic importance to anyone responsible for the care of this complication. Obviously, the treatment will be almost exactly reversed depending on which view is favored. These reports, which appeared while many of these patients were under treatment, afforded no comfort. In spite of a reevaluation of results with these arguments in mind it could be concluded only that extremities presenting varying degrees and extent of vasospasm were clinically improved by sympathetic paralysis. Not only were surface changes noted but also pulses improved, discomfort decreased and activity increased. The treatment was therefore continued, pending further study. The relation of the deep and surface circulations will stand further investigation, but a reversal of the treatment of vasospasm does not seem to be indicated.

Clinically, the indication for sympathetic paralysis is the presence of vasospasm — in fact,

block is a therapeutic test for the presence of vasospasm as distinguished from mechanical occlusion. If, in an ischemic extremity, one could be certain that the impairment was organic and fixed with no spasm of the collateral vessels, there would be no point in attempting to alter the distribution of this fixed supply. Clinical improvement following sympathetic block is believed to indicate the presence of vasospasm, and there is increasing evidence that it complicates peripheral injury and disease more frequently than has been appreciated.

SUMMARY

Vasospasm of varying severity and obstinacy may complicate peripheral injuries, particularly those in which there is an element of concussion involving increased tissue tension.

Neither extensive injury nor involvement of nerves or blood vessels is necessary to the development of vasospasm.

Subjectively, there is local discomfort and resistance to function. Objectively, there is de-

creased surface temperature, blotchy cyanosis and diminished pulses.

A persisting, low-grade ischemia causes trophic changes that materially impair the functional result.

Two cases of traumatic arterial vasospasm in which sympathetic block resulted in clinical improvement are presented.

VAGINAL SMEARS AS AN AID IN THE DIAGNOSIS OF EARLY CARCINOMA OF THE CERVIX*

MAURICE FREMONT-SMITH, M.D.,† RUTH M. GRAHAM, B.S., AND JOE V. MEIGS, M.D.‡

BOSTON

OF the 17,000 annual deaths in the United States from uterine cancer the large majority are caused by carcinoma of the cervix. It has been stated that only 11 per cent of cervical cancers reach the surgeon in the early stage, and 60 per cent are completely inoperable when treatment is begun.¹ There is still an average delay of seven months from the onset of symptoms to the institution of treatment. Efforts to educate physicians and the public to the vital importance of immediate diagnosis and treatment at the onset of abnormal vaginal bleeding or discharge have been only partially successful. Moreover, even clinically early cases continue to show recurrence of the disease after operation or radiation.

It is possible that the entire concept of the life history of cervical cancer needs revision: that the so-called "early case" presenting a short history of bleeding or a minimal visible lesion is, in fact, already a moderately advanced or advanced cancer. It is possible that early cancer causes no symptoms and that diagnosis in the incipient stage would be followed in most cases by cure of the disease.

†Associate physician, Massachusetts General Hospital.

‡Clinical professor of gynecology, Harvard Medical School, chief of the Vincent Memorial Hospital (Gynecological Service), Massachusetts General Hospital, surgeon, Pondville Hospital, gynecologist, Palmer Memorial Hospital.

This hypothesis is substantiated by two recent reports. In July, 1946, Pund and Auerbach² published a study of 1200 cases in which the cervix was removed by hysterectomy for conditions other than cancer. Preinvasive cancer was found to be present in 47 cases (3.9 per cent), in addition several cases of unsuspected invasive cancer were found. The presence of cancer was not recognized from the gross appearance of the cervix in a single case. Only one out of 4 patients had had abnormal bleeding. The average age of the 47 women showing preinvasive cancer was thirty-six and a half years, in contrast to a second group of 50 consecutive biopsies showing invasive cancer, in which the average age was forty-eight and a half years. TeLinde³ found identical figures—a thirty-six-year average age for 11 cases of preinvasive as contrasted with an average age of forty-eight years for overt cervical cancer.

In September, 1946, Taylor and Guyer⁴ reported a case in which a biopsy of the cervix, taken in 1938, had been misdiagnosed. One pathologist reported epithelioma, transitional type, but he was overruled by a second pathologist, who believed that the tissue was insufficient for diagnosis. No operation was done. The patient had been examined every six months for seven years without the detection of any abnormality of the cervix. In 1945 a proliferative nodular lesion was seen on the cervix, a biopsy from

which showed early squamous-cell carcinoma with invasion. Preparation of additional sections from the tissue obtained seven years previously showed not only that cancer had been present but that (as in TeLinde's cases) beginning invasion had occurred in certain areas. The patient had been harboring cancer of the cervix without symptoms and without clinical evidence of the disease for seven years, and the clinical diagnosis seven years later was still "early carcinoma." Taylor and Guyer refer to Stevenson's⁸ cases, one developing "clinical cancer" eight and a half years and another showing microscopical invasion three years after previous biopsies had demonstrated noninvasive carcinoma of the cervix. Smith and Pemberton⁴ found an interval of four to six years between the discovery of early

In 1941 Papanicolaou and Traut⁹ described a new method for the diagnosis of uterine cancer. Technical details of this test are described in their publication, as well as in a previous paper from this laboratory.⁸ In brief, a dry pipette with capillary opening and capped by a rubber suction bulb is inserted into the posterior vaginal fornix, the bulb is released, and the pipette withdrawn. Fluid so obtained is blown upon a glass slide, fixed while still wet in equal parts of ether and 95 per cent alcohol and later stained and examined for cancer cells. Criteria for the recognition of cancer cells are given in the two publications referred to above.

Papanicolaou,¹⁰ in 1943, reported 7 cases of "intradermal" carcinoma of the cervix in which vaginal smears were positive for cancer. Ayre¹¹ described 19

TABLE 1 Pertinent Data in Cases of Cervical Carcinoma

CASE No.	AGE	SYMPTOMS	VAGINAL SMEAR	BIOPSY	PATHOLOGICAL DIAGNOSIS
1*	37	Occasional bleeding for 3 mo.	Positive	—	Carcinoma in situ

lesions by biopsy and the development of clinical cancer.

Rubin⁷ reports 2 cases of early squamous-cell carcinoma of the cervix. One patient was followed for seven years subsequent to a positive biopsy, with no symptom or sign referable to the malignant lesion. The other patient showed no clinical evidence of disease until five years after the original positive biopsy.

If there is a period of years before the appearance of symptoms during which cancer of the cervix is nevertheless present and capable of diagnosis by serial section of the excised cervix, there exists, if one could but make use of it, a critical period during which treatment should result in cure in all or in a high percentage of cases. Although such lesions are often detected by biopsy, a satisfactory biopsy specimen is difficult to obtain in early cases in which no suspicious area is visible or in which, as occurred twice in our series, the lesion is endocervical. The pathologist can report cancer only if an area containing cancer is provided him.

cases in which the interesting diagnosis of "pre-cancer" was made. Abnormal cells were found in the cervical secretions of these women. It is difficult to know whether these cases fall into the group discussed below. Hertig¹³ reports 8 positive and 5 negative smears in 13 cases of cervical carcinoma in situ.

In 1945 Meigs et al.¹² reported 3 cases of cervical carcinoma in situ in which vaginal smears were positive. Meigs¹⁴ reported from this laboratory 2 additional cases of preinvasive carcinoma of the cervix in which vaginal smears were positive. In the 12 cases of cervical carcinoma in situ reported below, vaginal smears were positive in 10.

In the total group of 17 cases, 14 patients gave a history of bleeding or discharge, and 3 were without symptoms — of these, 2 had positive vaginal smears (Table 1). Initial biopsies were positive in 4 cases, and in 2 the initial biopsy was reported "insufficient for diagnosis" — in 1 of these a second biopsy showed carcinoma in situ. The biopsy diagnosis was chronic cervicitis in 5 cases and leukoplakia in 1. No biopsy

was performed in 4 cases, and in another no biopsy specimen could be obtained. Thus, in 8 of 12 cases, the initial biopsy failed to disclose the presence of carcinoma in situ, whereas of 17 cases examined by vaginal smear, this test was positive in 15.*

The following are brief abstracts of the last 12 cases

CASE 6 H P (private case), a 71-year-old woman whose cervix had been repaired in 1920, had been given radium for flowing in 1923. There had been no hot flashes or other symptoms. Examination disclosed scarring of the cervix. Biopsy revealed no suspicious area. Vaginal smears on February 12 and June 4, 1945, were positive. A hysterectomy was performed on July 24 and at the midpoint in the cervical canal a polyp, 0.5 by 0.3 cm in diameter, was found. The pathological diagnosis was epidermoid carcinoma in situ.

CASE 7 S D (MGH 503466), a 42-year-old woman, complained of spotting preceding her periods. Examination disclosed an area of erosion about the os, with some bleeding at the lower margin. No suspicious area was seen. A vaginal smear was positive. The pathological diagnosis on a biopsy specimen was epidermoid carcinoma in situ.

CASE 8 R B (MGH 547504), a 43-year-old woman, had had a supracervical hysterectomy for menorrhagia of 2 years' duration $5\frac{1}{2}$ months previously. She complained of severe hot flashes. Vaginal spotting followed coitus $1\frac{1}{2}$ months after operation. A vaginal smear was positive. No biopsy was performed. The pathological diagnosis was epidermoid cervical carcinoma in situ.

CASE 9 S S (MGH 502116), a 63-year-old woman, had reached the menopause 15 years before admission. She had had no hot flashes. Bleeding for 1 day had occurred in June, 1945, and for 3 days in July. At biopsy on August 31 the tissue was insufficient for diagnosis, in another one, taken on September 7, the pathological diagnosis was epidermoid carcinoma of the cervix in situ. A vaginal smear on September 9 was positive. The final pathological diagnosis was epidermoid cervical carcinoma (? in situ).

CASE 10 A H (MGH 519079), a 57-year-old woman who had reached the menopause 4 years previously, complained of occasional vaginal spotting of 8 months' duration until a curettage in another hospital 1 month before admission. A vaginal smear in January, 1946, was unsatisfactory, a smear on February 5 was positive. The cervix appeared normal. No biopsy was performed. The final pathological diagnosis was epidermoid cervical carcinoma in situ.

CASE 11 A R (MGH 457627), a 38-year-old woman, had been informed of a precancerous lesion of the cervix by an Army medical officer on June 20, 1944. For 10 years she had noticed bleeding and pain after intercourse. A vaginal smear on August 5 was negative. A biopsy on August 7 revealed chronic endocervicitis. The pathological diagnosis on the excised uterus was epidermoid cervical carcinoma in situ.

CASE 12 M D (private case†), a 39-year-old woman, complained of staining for 10 days. Biopsies on September 28 and October 6, 1944, revealed carcinoma in situ. A vaginal smear on October 24 was positive. The pathological diagnosis was squamous-cell cervical carcinoma in situ (? early invasion).

CASE 13 K W (private case), a 38-year-old woman, had had regular periods but intermenstrual bleeding for 3 months. The cervix showed a small area of leukoplakia. No tissue was obtainable for biopsy. A vaginal smear on November 12, 1946, was positive. The pathological diagnosis was epidermoid cervical carcinoma in situ.

*A slide in another case was sent to this laboratory from the Free Hospital for Women. The smear was thought to be negative, although a pathological diagnosis of cervical carcinoma in situ had been made.

†Reported through the courtesy of Dr. Paul A. Younger.

CASE 14 K T (MGH 130139), a 57-year-old woman, complained of an increase in vaginal discharge of 3 months' duration. There had been no blood. The cervix appeared normal to inspection. A vaginal smear on February 24, 1947, was positive. Biopsy on March 21 disclosed epidermoid carcinoma in situ.

CASE 15 H V (private case), a 49-year-old woman with no symptoms, after 3 months of treatment with estrogens for arthralgia noted 1 day of spotting. A vaginal smear on November 27, 1946, was positive. Biopsy on December 16 revealed chronic cervicitis. The pathological diagnosis was carcinoma in situ.

CASE 16 P F (MGH 545101), a 42-year-old woman, was admitted for a mass in the breast that proved to be due to chronic cystic mastitis. There were no pelvic symptoms. Examination showed an area of leukoplakia on the cervix. Vaginal smears on December 10, 12 and 21, 1946, were positive. Biopsy on December 14 disclosed leukoplakia. The pathological diagnosis on the excised uterus was cervical carcinoma in situ.

CASE 17 D T (private case), a 31-year-old woman, had had continuous flowing for 4 months. There was a rough area on the left lip. A vaginal smear was negative. Biopsy revealed chronic cervicitis. The pathological diagnosis was cervical carcinoma in situ.

SUMMARY AND CONCLUSIONS

Twelve cases of early cervical carcinoma are reported in which the vaginal smears were positive for tumor cells in 10. Two of these patients had had no symptoms referable to the lesion. In 9 cases in which biopsy was performed, a diagnosis of cancer on the initial specimen was made in only 3.

Preinvasive carcinoma exists for several years before clinical evidence of the disease appears. When a carcinomatous lesion of the cervix manifests itself by symptoms it is often no longer in the early stage. Early diagnosis is essential if cancer of the cervix is to be cured. Diagnosis of preinvasive carcinoma of the cervix is possible by study of the vaginal smear.

AN OUTBREAK OF SMALLPOX IN AMERICAN MILITARY PERSONNEL IN JAPAN

HORST A. AGERTY, M D *

PHILADELPHIA

SMALLPOX, an ancient disease whose prevention has been so readily achieved since the days of Jenner, continues to manifest itself. Even in some parts of the United States the record is shameful. A number of states, especially in the West and Northwest, do not have compulsory vaccination laws. In 1924 Minneapolis had 860 cases, with 219 deaths. In 1931 a total of 30,232 cases were reported from the country as a whole. More recently, however, the morbidity figures have markedly declined, there having been reported only 346 cases in this country in 1945.

Most physicians have never seen a case of smallpox, particularly those who practice in states in which vaccination laws are rigidly enforced. Furthermore, the majority of cases that have been described in this country in recent years have been relatively mild. On the other hand, North Africa and the Far East, especially India, are hotbeds of hemorrhagic smallpox.

Unquestionably, the health of the armed forces during the recent conflict was the best ever on record. The program of preventive medicine as outlined and carried out was generally quite adequate. Consequently, an outbreak of smallpox among American troops stationed in Japan came as a surprise and as a rude jolt.

Smallpox, an acute infectious disease of virus etiology, is highly contagious and is transmitted from man to man and by fomites. Standard textbooks present a full discussion of the etiology, incidence, pathology and diagnosis. The case reports presented below, however, will serve to clarify, illustrate and amplify virtually all aspects of the disease.

During January, 1946, a total of 17 patients with smallpox were admitted to a station hospital. I was ordered to this institution at the time of the peak of the outbreak to lend assistance. Since this afforded a rare opportunity, a detailed report of these cases is considered justifiable.

CASE REPORTS

CASE 1 This man was on duty in December 1945 in a Japanese town. In his duties which consisted of guarding and inspecting a Korean repatriation area he came in contact with countless natives. Several cases of smallpox among civilians had recently occurred. On December 17 the patient was admitted to a medical battalion clearing station because of complaints later shown to have been the prodrome of smallpox. On December 19 a rash broke out. Several days later the diagnosis of smallpox was made. The course was stormy; hot the patient began to improve, and on January 12, 1946, he was transferred to a station hospital for convalescence.

At that time, he was almost entirely free from crusts. The patient stated that he had been vaccinated to childhood but he recalled no definite "take," nor did he remember having had a scar on either arm. A vaccination to August, 1944 while he was in the Army, did not appear to have been successful.

CASE 2 This man was in the same ward in the medical battalion clearing station as the patient in Case 1. He had a cellulitis of the left ankle at the time of that patient's admission. On December 29 he was vaccinated. On the next day he began to develop symptoms that eventually showed themselves to have been the prodrome of smallpox. On January 2 he was transferred to the station hospital without a definite diagnosis. A reaction to the vaccination was suspected. The patient, however, was isolated on the fourth floor of the hospital. Medical aseptic technique was said to have been employed. On January 6 the diagnosis of smallpox was made. Two days later the patient expired of hemorrhagic smallpox. The vaccination on entrance into the Army was reported to have been "immune." A childhood vaccination had not been successful.

CASE 3 This man was one of a series of patient contacts in the station hospital. (There was no history of any direct contact with the patient in Case 1 who had been isolated, but epidemiologically speaking there is no other plausible explanation for these cases.) He was admitted to the station hospital on December 2 with the diagnosis of infectious hepatitis. He was placed in the hepatitis ward on the fourth floor. On January 14 he developed symptoms that were later shown to have been the prodrome of smallpox. Three days later a rash appeared. The patient was isolated. He ran a typical course of severe postular smallpox, from which he convalesced slowly. He recalled a childhood vaccination but could not remember whether it had been successful. In July, 1944 a vaccination done to the Army had apparently been unsuccessful.

CASE 4 On December 30 this patient was admitted to the third floor of the station hospital with the diagnosis of malaria. He received routine antimalarial therapy, and on January 8 he was returned to duty. Six days later he developed prodromal symptoms of smallpox. On January 16 he was readmitted to the hospital. He was again placed on the third floor. He developed a rash on January 18 and expired from hemorrhagic smallpox on January 23. A vaccination on November 28, 1944 had been reported as "immune." A childhood vaccination at the age of 7 years was said to have been successful.

Autopsy Post mortem examination disclosed the shotty, hemorrhagic, umbilicated vesicles covering most of body confluent on the face, chest, abdomen and proximal portion of the extremities. The lungs showed congestion, edema and hemorrhage in all lobes. There was acute, hemorrhagic tracheobronchitis. Petechial hemorrhages over all the pleural surfaces were observed. Petechiae were scattered over the pericardium and endocardium. There was mild endocarditis. The gastrointestinal tract showed petechial hemorrhages and superficial erosions of the esophagus, stomach and the small and large intestines. A moderate hepatomegaly with diffuse fatty changes in the middle and central zones, was observed. The genitourinary system revealed chronic interstitial nephritis, bilateral with massive hemorrhagic hemorrhage into the renal pelvis congestion and cloudy swelling. There was bilateral ureteral congestion and hemorrhage as well as blood clots in both ureters and in the bladder. There were petechial hemorrhages of the bladder mucosa. Acute orchitis with interstitial congestion and hemorrhage was noted. Petechial hemorrhages were observed over the tunica vaginalis. There was a moderate splenomegaly.

CASE 5 On January 4 this man was admitted to the third floor of the station hospital with a diagnosis of malaria.

*Associate professor of pediatrics, Haberman Medical College visiting pediatrician, Haberman Hospital and St. Luke's and Children's Medical Center; chief of pediatrics, Doctors' Hospital.

became worse, and blood-streaked sputum was seen. Numerous small gray ulcerations were observed in the tonsillar fossa at that time. Hematuria set in but was of a lesser degree than that in the other hemorrhagic cases. The cough became worse, the condition became critical, and the patient expired rather suddenly. There was no characteristic fall in temperature at the time of the onset of the rash.

Purpura variolosa Eight of the fatal cases were of the purpura-variola type. After the prodromal period, these patients uniformly presented a scarlatiniform flushing of the face, neck and chest. The extremities showed a mottled, reddish appearance. Subconjunctival hemorrhages were seen early. About thirty-six to forty-eight hours later the patients exhibited a purpuric eruption that was more or less generalized, not marked on the face but especially prominent on the chest, forearms, feet and legs. At about that time the face and extremities (especially the arms) became edematous, the eyelids swelled, and the conjunctivas were markedly hemorrhagic. Large quantities of thick mucus streaked with blood were raised, cough was marked, and efforts to swallow were frequently unsuccessful. Drooling occurred. The voice was thick and weak. Enemas yielded returns of bloody water. The sites of injections bled for minutes to hours. After several days vesicles formed, especially on the chest, with a few on the extremities. Some of the vesicles were hemorrhagic.

Three patients took on a slate-gray appearance. Four had small, closely spaced vesicles over the chest and extremities.

All fatal cases exhibited coarse, moist rales and rhonchi in the chest. The patients became extremely toxic. Large blebs on the wrists and ankles were noted prior to exitus in 4 cases. Two patients never developed much of an eruption, except for the slate-gray hemorrhagic appearance.

As the exitus approached, the patients became extremely stuporous. Respirations were somewhat labored, and coarse, moist rales were audible even without the use of a stethoscope. The impression was obtained that the patients were overwhelmed by the infection.

THE THERAPY

Hemorrhagic Cases

It is at once apparent that there is still no satisfactory therapy for the hemorrhagic cases. The mortality is virtually 100 per cent. In this series there were no recoveries. All the patients in this group received penicillin therapy. At first, the dose was 20,000 units intramuscularly every three hours. Later, this was increased to 40,000 units a dose. There was no tangible effect from the penicillin therapy. Daily blood transfusions were given in amounts of 150 cc daily. The fluid intake was largely handled by the intravenous route, since the oral intake in these cases was greatly restricted owing to difficulty in swallowing. Each day, 2000 cc

of 5 per cent glucose in physiologic saline solution or 10 per cent glucose in distilled water was given. Plasma was administered in amounts of 250 cc daily.

Adrenocortical extract was also given to 5 patients. No visible benefits were seen. Vitamins K and C were also administered, the intravenous route being utilized for the most part. The first patient to convalesce was employed as a donor for the other serious cases. Ten cubic centimeters of his whole blood was given twice to 5 of the seriously ill patients. This amount was no doubt inadequate.

Locally, various preparations were used. Petroleumatum, sodium bicarbonate and plain calamine lotion were tried. It was difficult to furnish relief. All the patients complained that the light hurt their eyes, and a darkened room afforded them much relief. A 10 per cent solution of mild silver proteinate was instilled into the eyes several times a day.

Aspiration, oral hygiene, sedation and oxygen therapy were employed on indication. It is obvious that none of these measures were helpful in preventing the final outcome of the disease. In these cases, despite modern science, one stands by helplessly at the sick bed. The situation is characteristic of that in many virus diseases: once the cells have been invaded, therapy is generally of no avail.

Pustular Cases

In these cases the advent of penicillin represents a therapeutic advance. Although it is difficult to draw definite conclusions from the cases presented above, the employment of penicillin is certainly logical. The pustular stage should indeed be favorably influenced by this antibiotic. Blood transfusions and parenteral therapy were given when needed, as were local applications and other palliative and supportive measures.

Mild Cases

The treatment in these cases was minimal. One patient received penicillin therapy for three days.

DISCUSSION

In the study of these cases there were a number of interesting factors for consideration. Unfortunately, a post-mortem examination was possible in only 1 case. Facilities for autopsy were poor, and in view of the highly contagious nature of the disease, it was considered prudent to minimize exposure. It must be pointed out that at the time of the outbreak the situation about the institution was one of some understandable uneasiness. The wide variety of the contacts instilled a wholesome awe for the ease with which the disease could be spread and even some doubt concerning the efficacy of vaccination. Fortunately, the value of smallpox vaccination was again demonstrated beyond doubt. Many of the unvaccinated patients had come from states where compulsory vaccination laws exist. In the 3 mild cases clear-cut histories of childhood

vaccination were obtained. Two patients still showed a scar. A vaccinoid reaction within a three-year period prior to the attack was recorded in 2 cases.

In the severe, pustular cases, the history revealed either an unsuccessful childhood vaccination or none at all. Vaccinations done within a three-year period were recorded as "immune" reactions in 3 cases. In another case no record was available.

In only 1 of the fatal cases was there a fairly reliable history of a successful childhood vaccination. Four patients apparently had received no childhood vaccination, and the remaining 5 provided an unreliable history. The severe eruption made identification of any old scars impossible. In 8 of the fatal cases the patient had had an "immune" reaction within three years of the illness. In 1 case the reaction was reported as "vaccinoid," and in another the immunization register was unobtainable.

Despite the incompleteness of some of the vaccination data, however, certain points stand out. Vaccination is not so universal in the United States as one might think. Even in states with compulsory vaccination laws there seem to be many slips. It seems to be fairly well established that vaccination in the armed forces has not always been performed with sufficient care—especially regarding the recording of reactions. Interrogation of some of the patients caused doubt whether they had ever received successful vaccinations in their lives. There had at times been a tendency to fail to read and to interpret the vaccination properly. It seems quite certain that many "immune reactions" should have been recorded as "no take."

In addition, it is apparent that even successful vaccination does not necessarily confer lifelong immunity. A successful childhood vaccination, however, frequently prevents the attack from becoming hemorrhagic. Whenever an area in which cases of smallpox have occurred is entered, all persons should be vaccinated without delay.

The universal revaccination of all troops and personnel, the enforcement of a working quarantine on the hospital and the strict isolation of all cases, contacts and suspects quickly terminated this outbreak.

The high degree of contagion of smallpox is again demonstrated. All but 3 of the cases were definitely related to Case 1. This fact, however, indicates that the contact need only be fleeting. Presumably, the effectiveness of the isolation technic used at the station hospital was average, although breaks obviously occurred. On the other hand, there seems

to be no reason to assume that smallpox is spread in a mysterious way by winds blowing from "pest houses" and the like. Medical aseptic technic employed by an adequately vaccinated personnel, with the patient completely isolated, should afford adequate protection. It is gratifying and reassuring to note that none of the physicians, nurses or attendants in intimate contact with these patients contracted the disease. Such persons were promptly revaccinated.

Until the fact of an epidemic has been established, the diagnosis of a case early in the disease is frequently difficult. This applies especially to the hemorrhagic cases, with their early scarlatiniform flush. Many of the cases also resembled measles. The mild cases naturally bring up the question of chicken pox. The long prodromal period is of help in suggesting the possibility of smallpox.

Apparently, hemorrhagic smallpox is merely a severe form of the disease. There seems to be no validity in postulating a hemorrhagic strain of the virus, since all varieties of smallpox originated from the same source. It is probable that the degree of exposure and the extent of the immunity had a bearing on this matter.

The incubation period in these cases averaged about two weeks, which is in harmony with the usual experience. The time can be less than that period, however, and also of greater duration.

SUMMARY

An outbreak of 17 cases of smallpox, with 10 deaths, is reported and discussed.

Hemorrhagic cases are highly fatal, representing a 100 per cent mortality in this series.

Penicillin therapy is of promise in cases of the pustular variety.

The high degree of contagion of smallpox is again demonstrated.

The difficulty of early diagnosis is emphasized, especially among the first cases of an outbreak.

Vaccination is still the only satisfactory answer to the problem. A scrutiny of the vaccination history in these cases showed that the protection had been inadequate for the most part.

In the face of actual cases, the entire personnel must be revaccinated.

Fresh vaccine, proper vaccinating technic and the correct interpretation of the reactions are essential to an effective program of prevention.

HEMOGLOBINEMIA ACCOMPANYING TRANSURETHRAL RESECTION OF THE PROSTATE*

ERNEST K. LANDSTEINER, M.D.,† AND CLEMENT A. FINCH, M.D.‡

BOSTON

THE removal of the prostate by the transurethral method, together with newer methods of preoperative and postoperative care of the patient by the use of fluid therapy and antibiotics, has increased the number of patients who may safely be subjected to prostatectomy. In spite of the present refinements, transurethral resection carries an appreciable — although low — mortality. One of the disturbing complications sometimes noted is a temporary oliguria or even anuria. A fatal case of renal failure following transurethral prostatectomy called attention to the possibility that intravascular hemolysis played a part in its causation. The following is a brief abstract of this case.

A 62-year-old salesman was admitted to the hospital on July 5, 1945, because of inability to urinate of 12 hours' duration. He gave a history of increasing prostatism during the preceding year.

Physical examination was negative except for a blood pressure of 200/110 and a markedly distended bladder. The prostate was enlarged about twice the normal size on rectal examination, but showed no evidence of cancer.

Examination of the blood revealed a hemoglobin of 9 gm per 100 cc and a white-cell count of 9800, with a normal differential count. The urine, which showed a specific gravity that ranged between 1.006 and 1.012, gave a +++ test for protein, the sediment contained an occasional red and white cell. The blood urea nitrogen was 8 mg per 100 cc, and the phenolsulfonephthalein test showed 39 per cent excretion of the dye in 30 minutes and 65 per cent at the end of 2 hours.

After catheterization the patient was able to void spontaneously, and on the 4th hospital day a transurethral prostatectomy was performed under combined spinal and Pentothal anesthesia. A moderate amount of bleeding occurred during the resection, and a transfusion of 500 cc. of citrated blood, found on crossmatching to be compatible, was given while the operation was in progress. This was followed after operation by 1000 cc of distilled water containing 5 per cent dextrose, and later a second transfusion of 500 cc. of citrated blood was given because of continued bleeding and a low blood pressure. A sample of serum obtained before the second transfusion, for the purpose of crossmatching, was observed to show marked hemolysis.

On the 1st postoperative day the patient appeared ill, he was restless and nauseated, and the urinary output was low. Bleeding was slight. The blood urea nitrogen was 65 mg per 100 cc. In the afternoon the blood serum showed a hemochromogen level§ of 199 mg and a total bilirubin of 2.08 mg per 100 cc. On the 2nd day the hemochromogen level was 130 mg and total bilirubin 0.77 mg per 100 cc, and 3 days later the hemochromogen level was 33 mg per 100 cc.

Throughout the 1st postoperative week the patient produced only a small amount of urine, the total output being

about 1500 cc. The blood urea nitrogen rose to 90 mg per 100 cc on the 3rd and to 120 mg on the 5th postoperative day. During that time the patient received supportive therapy, which included intravenous fluids, whole blood, plasma and amino acids, since he was unable to take anything by mouth. On the 8th day a diuresis of 1400 cc occurred. Thereafter, the patient maintained an output of over 2000 cc. of urine daily, but the specific gravity was persistently low, and the urea concentration of the urine varied between only 121 mg and 285 mg per 100 cc. (normal 2500 to 3000 mg). This, with blood urea nitrogen levels between 110 and 140 mg per 100 cc, demonstrated an almost complete lack of concentrating power on the part of the kidneys. On the 11th postoperative day the patient developed auricular fibrillation, dying on the next day of cardiac failure. Permission for autopsy was not obtained.

It seemed evident that in this case intravascular hemolysis, as demonstrated by an elevated serum hemochromogen level, was followed by hemoglobinuric nephrosis. An intrinsic hemolytic anemia seemed an unlikely cause for this reaction, since all laboratory tests, including cold hemolysis, acid hemolysis, hypotonic fragility, sickling preparation and cold agglutination, were within normal limits. The two transfusions of bank blood that the patient received had been rechecked for type and compatibility, and both were found to be compatible. One was Type O and Rh positive, and the other Type O and Rh negative, the patient was Type O and Rh positive. The small dose of sulfadiazine — 1 gm daily for four days — given preoperatively in the absence of other evidence of sensitivity, spherocytosis or abnormal agglutination did not account for the severe hemolytic reaction.

It was suggested that the operation of transurethral prostatectomy in itself was responsible for the hemolysis.¶ Accordingly, the blood of 15 consecutive patients undergoing transurethral resection was tested for the presence of hemolysis¶ by measurement of the serum hemochromogen level before and immediately at the close of the procedure (Table 1). All patients were operated on by the technic described by Nesbit.² A Bovie generator was used, and distilled water for irrigation was obtained from a reservoir about 75 cm above the level of the bladder.

In this group 10 patients (66 per cent) showed significant hemolysis, the blood hemochromogen levels after operation ranging between 24 and 316 mg per 100 cc. In 3 cases the level was over 200 mg per 100 cc — that is, within the range observed in the patient with renal failure described above.

¶This suggestion was made by Dr. Joseph Ross.

§A sample of blood was drawn from an antecubital vein, allowed to clot and centrifuged, and the supernatant serum separated within thirty minutes. All transfers of blood were made under mineral oil. Hemochromogen levels were determined by the method of Flink and Watson.¹

*From the Urological Clinic of the Peter Bent Brigham Hospital.

†Instructor in genitourinary surgery, Harvard Medical School, junior associate in genitourinary surgery, Peter Bent Brigham Hospital.

‡Instructor in medicine, Harvard Medical School, junior associate in medicine, Peter Bent Brigham Hospital.

§The blood hemochromogen level is a measure of all pyro iron pigments free in the blood stream, including not only hemoglobin but also methemoglobin, hematin and methemalbumin. The principal substance found free in the blood stream immediately after hemolysis has taken place is hemoglobin, but if determinations are made a number of hours later appreciable amounts of the other substances may also be found. These other substances are derived from the free hemoglobin originally present. The hemochromogen levels mentioned below are therefore a measure of the amount of hemolysis that had taken place.

All but one of the patients showing hemolysis made a good recovery and gave no evidence during this period of any renal damage or increased nitrogen retention as a result of the operation with its attendant hemolysis. One patient, however, with

second day, which returned slowly to normal after ten days.

At least two possibilities are suggested as the cause of the observed hemolysis: local action of the electric energy of the instrument on blood-contain-

*Blood given after hemochromogen determination

†Patient had oliguria for one day

a hemochromogen level of 220 mg per 100 cc, had temporary oliguria on the day after operation, despite an adequate fluid intake (3200 cc). This lasted for only about twelve hours, during which almost no urine was formed, and was followed by

ing tissues, and the penetration of the irrigating fluid (distilled water) into the blood stream either by lymphatic absorption or into venous channels opened by operation, with resulting hemolysis.

The first possibility seemed remote, in view of the absence of hemolysis in patients subjected to fulguration of bladder papillomas by the same type of electric current as that used in the resectoscope.

To investigate the possibility that distilled water used for irrigation during the resection gained access

to the blood stream, sodium salicylate, in amounts of 1 gm per liter, was added. This substance was chosen to label the irrigating fluid, since a method of accurately determining its presence in small amounts in the blood has been described by Brodie et al.¹ Also, it was found that in this concentration in the irrigating fluid, sodium salicylate caused no interference with the cutting action of the resectoscope. The blood levels of sodium salicylate to be expected an hour after the administration of varying amounts of this drug were investigated in several patients prior to its use in transurethral prostatectomy (Fig. 1).

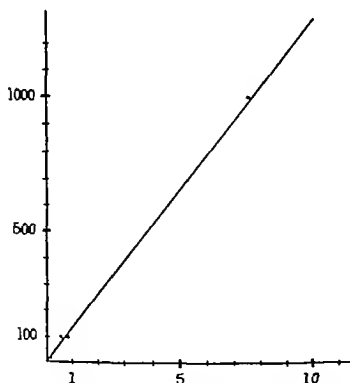

FIGURE 1 Sodium Salicylate Blood Levels following the Intravenous Injection of the Drug

The ordinate represents the amount of drug injected (in milligrams) and the abscissa the blood level (in milligrams per 100 cc) one hour after injection.

a diuresis lasting for two days with an output of over 2000 cc on each day. The damage to the kidneys was reflected by a postoperative rise in the blood urea nitrogen to 53 mg per 100 cc on the

Three patients were subjected to transurethral prostatectomy, an irrigating fluid containing 1 gm of sodium salicylate in 1000 cc of distilled water being used. In 2 cases no sodium salicylate could be demonstrated in the blood, nor was there any hemolysis. The third patient, in whom a large amount of hemolysis occurred, — a hemochromogen level of 316 mg per 100 cc, — also showed the presence of sodium salicylate, the blood hemochromogen level at the end of operation being 7.5 mg per 100 cc. This level of sodium salicylate is to be expected an hour after the intravenous administration of about 1 gm of this substance and therefore represents the entrance of about 1000 cc of irrigating solution into the blood stream.

In the patients studied it has been assumed that the distilled water entering the circulation caused hemolysis of the blood. Such a fluid is well known to be hemolytic for red cells in vitro. Krumbhaar,⁴ in experiments on dogs, found that the intravenous injection of distilled water of 2 to 3 per cent of the body weight produced hemoglobinemia and hemoglobinuria, and that the speed of injection — from three to forty-five minutes — had little effect on the amount of hemolysis. To check the validity of these data for man, distilled water was given intravenously in amounts from 100 to 900 cc to several patients. The smaller amounts were given rapidly over one or two minutes. The larger amounts (300 to 900 cc) were given slowly over a period of one to four hours. Appreciable hemolysis was produced in every case (Table 2). In no case was there any reaction or evidence of renal dysfunction after injection. The data suggest that amounts of distilled water in the neighborhood of 500 cc or more are necessary to produce hemoglobinuria.

Discussion

Intravascular hemolysis is a frequent consequence of transurethral prostatectomy. Evidence has been presented that distilled water used for irrigation gains access to the blood stream and that it is capable of producing the degree of hemolysis observed. The demonstration by Nesbit of free venous bleeding from veins of the prostatic capsule injured during operation makes it quite evident that these are a portal of entry for the fluid, when its pressure exceeds that in the veins. Although the fluid used for irrigation already contains hemolyzed blood, this accounts for only a fraction of the hemolysis observed.

There is no reason to believe that the renal damage resulting from hemolysis during transurethral resection differs essentially from other types of hemoglobinuric nephrosis. The pathogenesis of the renal failure in these conditions is not yet well understood, as pointed out by Bradley.⁵ Hemoglobinemia

is not the sole cause, for comparable hemolysis has been produced⁶ and comparable amounts of distilled water have been injected intravenously⁷ without causing renal damage. Probably, blood loss and renal ischemia^{8, 9} both of which may well occur during transurethral resection, play an important contributory role in the pathogenesis of the renal lesion.

Regarding the prevention of such hemolysis, in view of the possibility that fluid enters the circulation through venous channels opened during operation, the use of irrigating fluid under as low a pressure as possible and in as small a quantity as is consistent with clear vision is self-evident. The employment of a fluid such as physiologic saline solution, which is well borne in the general blood stream, is precluded because the cutting current of the resectoscope cannot be efficiently produced in a medium containing strong electrolytes. The addition of some nonelectrolyte, such as glucose, to the irrigating fluid has been tried but has not been found entirely satisfactory because of impaired vision.

SUMMARY

A fatal case of renal failure following transurethral prostatectomy is described. Death was caused by massive intravascular hemolysis occurring during the operation.

Fifteen patients undergoing transurethral prostatectomy were studied for the presence of hemolysis, by measurement of the serum hemochromogen level immediately at the termination of operation. In 10 cases a significant amount of hemolysis could be demonstrated, with extremely high hemochromogen levels in 3 cases, resulting in temporary oliguria in 1 patient.

Evidence is presented that this hemolysis is caused by the entrance of distilled water into the blood stream through venous channels opened during operation.

MEDICAL PROGRESS

INDUSTRIAL MEDICINE

IRVING R. TABERSHAW, M D *

NEW YORK CITY

INDUSTRIAL medicine in the first postwar year continued to show the influence of the lessons learned from the war. New ideas, new methods, new procedures and new viewpoints that originated in war experiences were encountered everywhere. The progress made may be divided into two groups, technical and social.

Technical advances were manifold and should prove of enduring value. General safety programs in many war industries reached a new high level, with gratifying results. In the munitions industry lessons learned from World War I were remembered and utilized, new experiences were added, and safety devices introduced that proved highly effective. As a result fatalities among munition workers during the war were remarkably small compared with the records of 1918. Industrial hygiene also profited from experiences in dealing with the hazards of radioactive substances of all kinds. The most dramatic achievement during the war — the liberation of atomic energy — has brought with it, and will continue to do so, new hazards to personnel employed in plants where this new force is generated. Safeguards have, on the whole, been unusually effective, and thanks to the war and the preproduction research, industrial hygiene has known methods to protect employees from dangerous exposures.

The social advances proved even greater than those won in the technical field. Experience has taught that mechanical safety devices by themselves are not sufficient to achieve the best results. The human element has also to be considered, and the co-operation of the group and the individual worker enlisted. Thus, a new concept has developed that of the worker as a "total man" whose mental and emotional traits and responses are as important for high productivity as his physical capabilities. Since these emotional responses depend not only on working environment but also on conditions outside the working place, another social development followed logically. Plant services were integrated with community health programs, and preventive medicine has become an important factor in ensuring not only the well-being and happiness of the worker but also an increase in his productivity. Management and labor alike are recognizing more and more the necessity and the value of industrial medical services. During 1946 a constantly growing co-operation of employer and employee in instituting

and maintaining an effective in-plant medical department has led to encouraging results. Also, workmen's compensation laws show a growing trend toward liberalization, and the "subsequent injury" law already adopted by thirty-two states is a progressive step in this direction, this law relieves the insurance carrier and the employer from being excessively liable when employing a handicapped worker, veteran or nonveteran.

In the educational field, industrial medicine has likewise made valuable advances. Many colleges and universities have recognized this branch of medical science and have instituted special courses to train competent industrial physicians and engineers. The need for providing medical services for the smaller plant has been appreciated, and numerous plans have been suggested by industrial physicians and agencies interested in the field of industrial medicine. One index of the general progress made in the field of industrial medicine is the increased employment of industrial nurses. In 1941 only 6000 nurses were doing industrial work, whereas in 1945 their number had risen to 14,000 — an increase of 133 per cent.

ATOMIC ENERGY AND PHYSICAL AGENTS

The fact that atomic power has been harnessed on an industrial scale for the first time in history brings the possibility of the more widespread industrial uses of atomic energy appreciably nearer and makes it of immediate importance to the industrial physician, who will have to face the new and difficult problems posed by nuclear energy. Bale¹ points out that until recently nuclear energy was produced only in large-scale operations at fixed sites where adequate methods of protection reduced to practically nothing the hazards to personnel. Health reports from Oak Ridge, for example, were uniformly good, and Clarke² states that the anxiety that working with radioactive materials might cause sterility is completely refuted by the birth rate at Oak Ridge, which was one of the highest of any city in the country. All these protective measures, however, have been expensive and have required the continued vigilance of the staff charged with the safety of the project.

Atomic energy will presumably be used in industry in nonmobile plants as a source of electricity, and as such it will have to compete economically with electricity derived from water power and from coal-burning installations. Despite the economic

*Assistant professor of industrial health, Columbia University School of Public Health; medical director, Eastern Region, Liberty Mutual Insurance Company.

necessity of cutting costs, the industrial physician and engineer charged with the health and safety of workers, as well as with the health and safety of inhabitants living in the neighborhood of nuclear plants, must insist on adequate protection and safety measures, even if the needed precautions may have to be more elaborate than ordinarily realized

Dowdy³ offers the reassurance that no insuperable difficulties stand in the way of adequate protection of workers and public alike, for the types of radiation encountered in the liberation of atomic energy are in the main not new either to physicians or to radiologists and physicists. The radium industry has for many years dealt with and overcome these problems. Only neutron radiation is a completely new type of radiant energy not previously encountered in industry. The enviable record of the Manhattan District Project, however, is ample proof that the hazards of production in this field need be no greater than those in many other industries.

Kennedy⁴ likewise states that although the high level of neutron and gamma radiations of nuclear matter represents a real hazard to operators, observers and bystanders and although these hazards, being inherent in the fission reaction, are not subject to elimination from the process, they are definitely subject to careful control.

In the extensive wartime industry of radium dial painting, in which workers were inevitably exposed to radium, work has been done to prevent the fatal anemias and osteosarcomas that claimed many victims after World War I. In a discussion of the medical status of such workers Tabershaw⁵ presented a comprehensive survey of 52 radium dial painters who worked a minimum of eighteen months in applying luminous paint. Their physical and dental conditions, their blood counts and their nutritional status were recorded, and the conclusion reached that reliance on medical examination is not sufficient to control the hazard. Only regular breath-radon analyses at intervals of six months or, in certain cases, of even three months, combined with an educational campaign regarding work habits, personal hygiene and care of teeth, can prevent deleterious effects.

Beta and gamma radiation is dealt with in a paper by Evans⁶. In textile and paper mills it is often necessary to install radioactive static eliminators as a safety appliance. These eliminators reduce the hazard of fire or explosion of chemical vapors by eliminating the possibility of electrical sparks due to static electricity. These safety appliances, however, being radioactive, present in themselves a new industrial hazard owing to the penetrating radiation that they may emit. Since the radiations that are generated and the maximum permissible doses are known, it is simply an engineering problem to provide adequate safety measures. Shields, sufficient distance and even magnetic deflection are recommended. The commercial de-

velopment of alpha-ray sources (plutonium, protactinium or polonium) that, unlike radium, emit few or no beta or gamma rays may in the future become a problem.

Injuries resulting from exposure to radioactive substances and roentgen rays are discussed by Dunlap⁷. The main hazards are encountered in plants where x-ray or radiologic equipment is manufactured or radioactive substances used. Safety measures consist in the elimination of all unnecessary exposures by the use of adequate lead shielding, long-handled instruments, speed in carrying out dangerous operations, the rotation of workers and, finally, careful medical supervision.

Out of Hanford also comes a most interesting paper by Cantril⁸ on the use of radioactive tracers in industrial medicine. The method of employing a small quantity of a particular radioactive isotope to trace or tag the chemical flow or metabolic patterns in a chemical or physiologic process is not new and was used in various fields prior to the development of atomic energy. This procedure has been employed not only in physiology but also in industry. In the control of exposure of radium dial painters to radium it was possible to use the radioactive properties of the noxious agents in measuring the quantities of contamination on benches, floors, hands and so forth or in the air. The experienced industrial hygienist will with a little imagination recognize the possibilities of applying these technics to occupational hazards quite unrelated to the field of radioactive materials. A tracer could be found that, by virtue of its radiations, half-life and metabolic properties, would measure contamination of working locations and personnel. The method, however, will have to be controlled, not to substitute a radioactive toxin for a nonradioactive one.

The effects of electric injuries, with particular reference to the nervous system, are considered by Hyslop⁹. Accidental deaths from electricity (not due to lightning) represent 0.9 per cent of all accidental deaths, and about 0.4 per cent of all accidents in industry and in the home. Approximately 17 per cent or about 1 electric accident in 6 is fatal. Vital organs and tissues traversed by the current may be functionally impaired or even destroyed, and although other parts of the body may be affected with resulting functional or structural damage, persisting psychoneurotic reactions, as well as a permanent total disability, are rare. Electricity, in contrast to damage done by radium or radioactive substances, does not cause progressive dissemination or local degenerative structural defects.

THE SMALL PLANT

Industrial hygiene and industrial medicine are as necessary for the small plant as for the great industrial concerns. These small plants, however, which Bloomfield¹⁰ calls "the underprivileged members of

the economic system," are often not able to provide an adequate medical department for health protection and health maintenance of their workers. It is essential that the achievements of modern industrial hygiene be made available to the small plant, for two thirds of American workers are employed in such plants. National and community health agencies in various states have therefore united with the small-plant employers and employees to bring about an improvement of worker health through control of his environmental hazards and his individual health problems. Millman et al.¹¹ report on the work of the Industrial Health Unit of New York City. Seven small plants, varying in size from 70 to 700 employees who had either inadequate or no health service, participated in the program. The results were satisfying. A program of this kind has proved to be economically feasible provided that proper plant organization can be installed and that official as well as unofficial community groups take an active interest in the success of the undertaking.

In California an industrial group — F. M. Poole, M. D., and Associates — has been formed to serve the industries in the growing industrial San Fernando Valley.¹² The staff of the group includes six physicians with extensive industrial experience, and the aim is to develop a comprehensive industrial medical plan designed specifically to benefit a variety of industries and plants of various size, down to the smallest, employing as few as ten workers.

How necessary it is to institute such health services for small plants and to enlist the interest of management, labor and community agencies in creating and maintaining it was proved by a survey conducted by the Bureau of Industrial Health of the State of New Jersey. Hazard¹³ states that the results show that only 1 plant out of every 5 employing 101 persons or more and only half the plants employing 501 persons or more had adequate doctor service. Among plants employing 101 or more apiece 54 per cent did not offer physical examinations for either placement or health improvement, 65 per cent had no adequate plant food service, and nearly half — 43 per cent — were without a nurse.

Strong¹⁴ insists that best results can be maintained if plant health service is based on the co-operation of management, labor, public-health agencies and special health agencies, which, in a common effort, can provide the protection and the medical care for the workers that the small plant is economically unable to afford. The installation and maintenance of a first aid kit under the control of one or more employees, especially trained in first aid techniques, is suggested for the small plant, store or shop where only 10 workers or less are employed. Although the careful maintenance of such a first-aid kit is unquestionably most important, however, it is un-

fortunately true that the indifference of both employer and employees probably makes such a kit often not only useless but a danger instead of a help.

In preventive medicine the small plant is also under a disadvantage compared to the large, industrial concerns. Pollak¹⁵ compares conditions regarding tuberculosis in the Caterpillar Tractor Company, of Peoria, Illinois, with those in smaller plants in the same area that do not maintain a full-time medical department. In the survey of 13,547 employees of the Caterpillar Tractor Company, the incidence of active pulmonary tuberculosis was 0.16 per cent. On the other hand, in the smaller plants covered by the same survey, of 12,129 employees given x-ray examinations, the case incidence of active pulmonary tuberculosis was 0.29 per cent, or nearly twice as high as that in the group that enjoyed the industrial health protection of a competent and comprehensive medical service.

The problem of the small plant in industrial medicine, being chiefly an economic one, must be solved by the co-operation of all concerned, including management, labor and the official and non-official health agencies.

JOB PLACEMENT

During the war, virtually all able-bodied men having been taken into the armed forces, industry had to maintain vital production with a labor supply recruited from the ranks of the physically handicapped, the superannuated and women. It was found, however, that these physically inferior workers could and did achieve an excellent production record. The problem of the physically impaired worker has lost nothing of its urgency and significance in the postwar period.

Out of the war a new concept of industrial physical fitness has evolved: a worker is physically fit if he can do a good day's work. Harvey and Luongo¹⁶ point out that the capacity for work is a relatively untouched problem and that medical science does not yet possess a method of evaluating it correctly. Ultimately, such capacity rests on the reserve compensation that the personality of the disabled worker provides. The examining industrial physician must therefore possess a certain diagnostic flair and must be able to judge the reserve compensation behind the visible fact of physical impairment. Although many doctors have evolved their personal formulas regarding the job placement of the handicapped, illuminating their rules with detailed charts, the insight of the examining physician will in the end prove of greater value than any purely schematic approach. In general, it is recommended that any doubt should be resolved in favor of the applicant, since the desire for the work oftener than not creates the capacity to perform the work. All studies on properly placed handicapped workers indicate that they are on a par with their able-

bodied fellow workers Training and placing costs are balanced by the fact that the handicapped workers stay on the job longer than the average able-bodied worker

Back strains, representing one of the most important problems in industrial medicine, have been investigated by Parton and Biram¹⁷ These authors report on a series of a thousand consecutive routine roentgenograms of the lower back taken as part of a preplacement examination, 502 cases were considered normal, and anomalies were revealed in 498 The authors believe that these deformities play a significant role in the decompensation of backs in the age group over forty-five years, and in spite of the lack of knowledge regarding correlation with job placement, preplacement x-ray examination is useful These studies are in accord with similar studies by other investigators

Industry has to deal not only with disabled veterans and workers but also with physically unimpaired workers and their various problems Ghiselly¹⁸ points out that the basic considerations in job placement and personnel procedures are not forms and schedules but rather men and women who have worked together in a complex social environment He also insists that job placement is not a static affair but a dynamic process that does not end with the assignment of a particular worker to a particular job New problems of adjustment, change in conditions and change in personality or attitude will constantly arise and make job placement a continuing process

Management has often found it advisable to employ a psychiatrist either in an in-plant or in a consultative capacity Clarke and Law¹⁹ state that a few progressive concerns have always availed themselves of the services of a staff psychiatrist, but during the past few years, psychiatry in the field of industry has made great headway Psychiatric appraisal of the personality of the workers has been found of great value, not only in job-placement but also to combat absenteeism, undue work termination and accidents, which are often due more to faulty human material than to flaws in the technical department

Clarke and Law, as well as Leggo et al²⁰ reporting on their work in industrial psychiatry done at the Oak Ridge community where the atomic bomb was developed, speak of excellent results among thousands of employees It was found that psychologic and psychiatric pre-employment screening and the application of psychiatric insight in job assignments gave uniformly good results Therapy for on-the-job patients who presented emotional disturbances proved especially profitable, for it prevented non-disabling maladjustments from developing into major disabling breakdowns Leggo et al also state that during their two years' work at Oak Ridge they almost never encountered a patient with a major psychosis The bulk of the case load con-

sisted of anxiety states, reactive depressions and psychosomatic reactions It is safe to assume that similar conditions prevail in industry in general, and that with a minimum of treatment conspicuous on-the-job improvement can be achieved Such improvement, implying as it does adjustment not only to work conditions but also to home environment, makes the employment of the psychiatrist in the industrial field a gain for the entire community.

DERMATITIS

Dermatitis continues to be the persistent problem of industrial hygiene, remaining in the forefront in the incidence of occupational diseases²¹ It is occasionally encountered in unexpected places and from unexpected causes It has been universally accepted that dermatitis arising from irritant dusts, mists and vapors only develops if the irritating agent comes into actual contact with the skin Baker and White²² report a case of occupational dermatitis due solely to the inhalation of trichloroethylene This solvent vapor, used as a degreasing material, was blown by several large fans directly into the open office of a foreman, who developed a severe dermatitis To establish that only inhalation and not penetration of the gas through clothing produced the dermatitis, the patient was sent to work wearing a gas mask When the mask was worn no skin irritation occurred, when the mask was discarded the dermatitis reappeared Installation of a ventilating system that dispersed the offending fumes through the roof cured the condition This is the first report of a case of generalized dermatitis produced solely by inhalation

It is generally accepted that scabies is transmitted only by direct contact. Fifteen women in a statistical department, however, contracted the disease through merely handling reports passed to them by a colleague suffering from the affliction, and the outbreak was deemed both occupational and compensable²³

A number of authors discuss the causes of occupational dermatitis Klauder and Hardy²⁴ report on an additional 539 cases as a supplement to a previous report of 1113 cases of cutaneous diseases²⁵ The review of 2297 cases gives a comprehensive picture of the various causes of occupational dermatoses These causes are divided into seven groups according to the actual causative irritant and not according to occupation, as is the more usual procedure The authors believe that the listing by causes helps in suggesting preventive and investigative measures and facilitates teaching of the subject The irritants resulting most frequently in occupational dermatitis were solutions used in electroplating and compounds of chromium, the highest incidence rate occurred in the printing trades, electroplating, tanning, the manufacture of textiles and dyeing Primary irritants accounted for 24.8 per cent of cases, and sensitizers for 12.5 per cent

Other causes were trauma, wet work, solvents, oil and chlorinated hydrocarbons. Lane,²⁴ in a review of compensation paid for disability due to occupational dermatitis describes a steady increase in the incidence of dermatitis but a reduction in the lost time, average indemnity and cost of medical treatment of these cases. Peck²⁷ found the chief causes of industrial dermatitis to be petroleum products and greases, alkalis, cement and solvents, in the order listed.

Keil et al.²⁸ proved by patch test that the same ingredients that produce poison ivy are responsible for the dermatitis caused by cashew-nut-shell liquid. Both plants are members of the same plant family, Anacardiaceae, and persons sensitive to one plant are sensitive to the other. Cashew-nut-shell liquid is an agent that causes a great deal of difficulty, especially in stevedoring operations.

Schwartz and his associates²⁹ have developed an entirely new technic to determine the value of various commercial ointments supposed to withstand penetration by alkali, acid or oil. Three standard substances and twenty-seven commercial products were tested, and on the whole it was found that anhydrous wool fat and white petrolatum are quite as efficient protective measures as the best commercial products. This was true for protection against alkalis and acids, as well as for oil. Other authors observed certain commercial products to be effective. Excellent results have been reported from the use of Paraprol,³⁰ — a product consisting of urea, lauryl sulfoacetate and benzyl alcohol, — which was tested on 300 employees and found to be effective both as a prophylactic and as a therapeutic measure, no unfavorable reactions from its use have been observed.

Preventive measures from another angle are suggested by Klauder and Brill.³¹ They attempted a correlation of the boiling ranges of some petroleum solvents with their dermatologic harmfulness. The irritant actions on the skin of petroleum fractions between kerosene and light spindle oil were dealt with, and the conclusion was reached that kerosene and solvents of lower boiling range invariably exert irritant action. The irritant action definitely decreased as the boiling range increased, and it therefore seems advisable to employ a product of as high a boiling range as possible consistent with the purpose for which it is to be used.

Protective clothing and personal hygiene are still of utmost importance to avoid undue exposure with resulting skin damage. Workers, as well as their foremen, must be educated to make conscientious use of the accepted preventive measures. Some of the methods used in the Army may be helpful in this educational endeavor. Personal or group talks, pamphlets, pictorial presentation and so forth can be utilized to explain and visualize the inevitable results of neglect and the equally indisputable rewards of proper care of the skin.

SPECIFIC CHEMICALS

In dealing with the toxicity of the vast number of chemicals used in industry, the industrial physician is, above all, on the outlook for new and improved means to determine at an early stage the deleterious effects. The thymol barbital test, which is reported by McCord and his co-workers,³² is therefore of particular interest as a means of detecting toxic effects of carbon tetrachloride. Functional impairment has taken place on levels lower than 100 parts per 1,000,000, and it is even possible that in some cases death occurred from apparently trivial exposures. In 1944 MacLagan,³³ of England, found, in the course of an inquiry on the colloidal-gold reaction of serum, that thymol, introduced for antiseptic purposes into the barbital employed as buffer along with certain serums, led to a turbidity apart from any action of the usual constituents of the colloidal-gold system. MacLagan³⁴ later established that this turbidity was quantitative and of diagnostic significance for hepatic dysfunction. McCord and his co-workers³² showed that this test is of value in determining the action of carbon tetrachloride on the liver and other tissues. An investigation was made on 712 hospital patients and 82 normal persons. The results indicated that the quantitative association of increasing turbidity with hepatic injury appears well founded. Exposure to low levels of carbon tetrachloride vapors may cause functional changes and even organic injury. In animals, concentrations of 40, 60 and 80 parts of carbon tetrachloride per 1,000,000 produced thymol turbidity.

Although this work helps to determine minimal injury, the difficulty of measuring carbon tetrachloride vapors in the air has also been practically solved. Sebayer and Ackerman³⁵ report a modified combustion method as used by the Army Industrial Hygiene Laboratory that permits the rapid and efficient determination of chlorinated hydrocarbon in air. Glass gas-sampling bulbs of capacities of 275 to 500 cc were used, and the collected vapors were burned in a modified sulfur lamp. The amount of hydrogen chloride formed was turbidimetrically determined with the help of a spectrophotometer. Four chlorinated hydrocarbons were studied, among them carbon tetrachloride, and it was found that concentration of vapor can be determined with an accuracy of 88 to 90 per cent.

Nutritional factors in industrial poisoning have been of interest for some time, especially regarding liver disease. Sbaifer, Carpenter and Moses³⁶ report that, although methionine is of undoubted therapeutic and prophylactic value in the protection of protein-deficient animals against carbon tetrachloride poisoning, it exerts no protective action against the liver damage of normal animals poisoned with carbon tetrachloride.

Volatile hydrides that have toxicologic importance are dealt with by Webster³⁷ Whereas many of these compounds have no industrial application, it is quite likely that the rapidly increasing production of the rarer inorganic chemicals will lead to the use of a number of volatile hydrides Many of these compounds are of an insidious character, entering the body through inhalation, and it is necessary to recognize the potential danger from breathing the substances

An extensive study of the effects of beryllium compounds is offered by Hardy and Tabershaw³⁸ Seventeen cases of a puzzling disease, which the authors call "delayed chemical pneumonitis," appeared among the employees of a firm manufacturing fluorescent lamps In the course of the manufacture beryllium compounds were used, and although no clear etiology has been established, the weight of evidence indicates that beryllium was responsible The fact that the 17 workers affected were employed in one building during the same period clearly points to common exposure The clinical features of the disease are a delayed onset, intense dyspnea, marked loss of weight and unfavorable prognosis The relation of the acute form of this disease to the more chronic type has not yet been defined

The increased use of tellurium in industry has awakened a deeper interest in the problem of its effect on the organism De Meio³⁹ reports a series of animal experiments in which tellurium was fed to rats Although the low toxicity of elementary tellurium, as opposed to tellurate and tellurite, was again established, it seems that long exposure to tellurium in great concentration tends to lower normal increase in weight and growth

Ethylene dichloride is a chlorinated carbon that is widely used as a solvent and for other industrial purposes An extensive literature dealing with its toxicity, its peculiar ability to render the cornea turbid and the effects of various protective agents already exists Heppel et al⁴⁰ report the effects of daily inhalations of this gas on a variety of animals The results indicate that dichloroethane is one of the more toxic of the frequently used hydrocarbons and should be employed only when proper precautions are taken

Ketones, alcohols, esters, ethers and miscellaneous solvents, all used widely in industry, are the subject of a study by Silverman and his associates⁴¹ in which sensory responses to these vapors were evaluated Sensory limits for eighteen organic solvents were established, and since eleven of these solvents had no previous evaluation of permissible concentration, the data offered are of special interest to the industrial hygienist and engineer

The report of a case of arsine poisoning by Hawlick and Ley⁴² should be mentioned Freshly diluted hydrochloric acid, which had been treated with an inhibitor containing a soluble arsenic compound, was poured through a water jacket The operation

was carried out in a poorly ventilated room, and precautions against inhalations of fumes were not observed The employee exposed to the fumes experienced after a few hours severe hemoglobinuria, prostration, jaundice, an enlarged and tender liver, peripheral neuritis and distinct hemolytic anemia The tentative diagnosis of acute hemolytic anemia secondary to exposure to a heavy metal, possibly a compound of arsenic (arsine), was confirmed when a specimen of the metal pipe through which the acid had been poured was tested by the Army Industrial Hygiene Laboratory

An effective agent against industrial poisoning with arsenic and mercury has been discovered in BAL (British antilewisite) This compound, which was developed during the war as an antidote for lewisite, has proved successful in the treatment of arsenic poisoning of any type The drug (2-3 dimercaptopropanol) is the best from the standpoint of skin penetration when used as an ointment. Although the least dangerous of the thiols, it is quite toxic, and its use must be carefully controlled

MISCELLANEOUS CONDITIONS

Penicillin in two different forms has been found highly effective in group medicine in both the Army and the Navy Agmar⁴³ reports a study in which crude penicillin was inoculated into surgical-gauze dressings This preparation proved dramatically effective for such minor infections as boils, carbuncles, secondary epidermophytosis of the feet, eye and ear infections, chronic ulcers of the leg and infected cyst Crude penicillin solution and penicillin gauze did not cause any reactions and worked more rapidly than the sulfonamides These preparations are easy to make, readily transportable, simple to use and markedly potent

Levitt and Leathen⁴⁴ are equally enthusiastic about penicillin lozenges in the treatment of oral infections One hundred and seventeen patients with acute infection of the nasopharynx and tonsils were treated with penicillin lozenges of 500-unit strength each Results of the treatment were excellent Of the 117 patients, 110 were cured rapidly, 87 of them on an outpatient status Only 7 patients did not respond to the treatment Five of these cases had tonsillitis complicated by cervical adenitis, which evidently proved that local concentrations of penicillin cannot penetrate tonsillar crypts or reach infections deep in the tissue of lymph nodes

A program of malarial surveillance for the industrial physician is offered by Shillito⁴⁵ Industrial concerns expanding their interests and activities into tropical countries and war veterans returning from these regions make it necessary for a medical department to become familiar with effective methods of handling this problem Two possible courses are recommended either a careful surveillance without drug therapy or a course of daily doses of quinacrine

MASSACHUSETTS MEDICAL SOCIETY

PROCEEDINGS OF THE ONE HUNDRED AND SIXTY-SIXTH ANNIVERSARY

May 20, 21, and 22, 1947

THE one hundred and sixty-sixth anniversary of the Massachusetts Medical Society was observed at the Hotel Statler in Boston on May 20, 21 and 22, 1947

Fifteen hundred and twenty-one physicians, one hundred ladies and two hundred and ninety-seven exhibitors were registered

The length of the meeting was increased this year by beginning the sessions in the morning of the first day instead of in the afternoon The Supervising Censors met in Parlor C at 4 30 p m on the afternoon of the previous day, May 19 This meeting was followed by the Cotting Supper in Parlors A and B, which was attended by 205 councilors The annual meeting of the Council was held in the Georgian Room at 7 00 p m with 189 councilors in attendance, as recorded in the attendance books

TUESDAY, MAY 20

The first general session, a symposium on industrial medicine, opened at 9 00 a m in the Georgian Room under the co-chairmanship of Dr. Daniel L. Lynch and Dr. Gerald L. Doherty

The one hundred and sixty-sixth annual meeting of the Society was held in the Georgian Room at 11 00 a m, President Dwight O'Hara presiding The attendance was about 450 Dr O'Hara spoke on "The State of the Society," after which the annual oration, "Medical Care in Our Free Society," was delivered

by Dr Leland S McKittrick The annual luncheon was served in Parlors A, B and C to 101 fellows

The second general session, a symposium on medical care for the people of Massachusetts, was held in the Georgian Room at 2 00 p m under the co-chairmanship of Dr Reginald Fitz and Dr Albert A Hornor The Shattuck Lecture was delivered at 8 00 p m by Dr William Dock, of Brooklyn, New York, on the subject "Clinical Significance of Circulatory Peculiarities of Some of the Vital Organs" (This lecture appeared in the May 22, 1947, issue of the *Journal*)

WEDNESDAY, MAY 21

The third general session was held at 9-00 a m under the co-chairmanship of Dr Isaac S F Dodd and Dr Allen G Rice

At noon certain of the sections held their luncheons, followed by their annual meetings The Section of Medicine, under the chairmanship of Dr Francis C Hall, met in Parlor A The attendance was 110 The Section of Pediatrics, under the chairmanship of Dr Hyman Green, met in Parlor B, with 60 members in attendance at the luncheon and 84 at the scientific meeting following The Section of Dermatology and Syphilology met in Parlor C under the chairmanship of Dr Jacob H Swartz, with 43 in attendance at the luncheon and 55 at the

meeting The Section of Physiotherapy met in the Hancock Room under the chairmanship of Dr William D McFee, with 15 members present

At 2:00 p m the fourth general session, a symposium on bronchiectasis, was held in the Georgian Room under the co-chairmanship of Dr Richard H Sweet and Dr Louis H Nason

The annual dinner was held in the Georgian Room at 7:00 p m, with 418 in attendance The speaker of the evening was Dr Harrison H Shoulters, president of the American Medical Association, who delivered an address entitled "The Responsibilities of the Medical Profession"

THURSDAY, MAY 22

The fifth general session was held in the Georgian Room at 9:00 a m under the joint chairmanship of Dr Franklin G Balch, Jr, and Dr Walter E Garrey

At noon the remaining scientific sections held their luncheons and meetings The Section of Surgery under the chairmanship of Dr Alexander J A Campbell met in the Salle Moderne, with 100 in attendance The Section of Obstetrics and Gynecology under the chairmanship of Dr William J McDonald met in Parlor A, with 60 in attendance The Section of Radiology under the chairmanship of Dr Edward B D Neuhauser met in Parlor C, with 39 in attendance The Section of Anesthesiology under the chairmanship of Dr Sidney C Wiggins met in Parlor B, with 42 members attending

The sixth general session was held at 2:00 p m under the joint chairmanship of Dr Howard F Root and Dr Gordon M Morrison

There were eighty-nine technical and four scientific exhibits

On Wednesday, May 21, at 2:45 p m the Massachusetts Medico-Legal Society held its meeting concurrently in Parlor C

At the annual golf tournament held at the Woodland Golf Club on May 20, the low gross winner was Dr R J Nugent, the second gross winner, Dr M Sargent, the winner of the low net, Dr A D Crowell, and the winner of the second low net, Dr G Quigley An exhibition of works of art by members of the Massachusetts Physicians' Art Association was on view throughout the meeting

The special list of officers, standing and special committees, councilors, censors, admissions and deaths is appended

JOSEPH GARLAND, Secretary

ANNUAL MEETING OF THE SOCIETY

The one hundred and sixty-sixth annual meeting of the Massachusetts Medical Society was called to order by the president, Dr Dwight O'Hara, in the Georgian Room of the Hotel Statler, Boston, at 11:00 a m., May 20, 1947 Approximately 450 fellows were present.

The Secretary submitted the record of the last annual meeting held on May 22, 1946, as published in the September 19, 1946, issue of the *New England Journal of Medicine* It was moved and seconded that the record be accepted, and it was so ordered by vote of the fellows present

The Secretary reported that the membership of the Society as of May 22, 1946, was 5989, and as of May 20, 1947, it was 6256 During the year there had been a loss of 140 fellows—95 by death, 42 by resignation and 3 by deprivation of membership There had been a gain of 407, of which 403 were new members and 4 had been reinstated It was moved and seconded that the report be accepted, and it was so ordered by vote of the fellows

At the request of the President, the vice-president, Dr Isaac S F Dodd, assumed the chair, and Dr O'Hara gave the following address

One may come to the office of president-elect and later president of the Massachusetts Medical Society supposing himself to be somewhat familiar with its routine affairs But when one finds himself an *ex-officio* member of thirty-odd committees and begins to see the various ways in which their many interests cross, he can hardly stand and marvel at the volume and the continuity of the work accomplished year after year in the name of the Society It is an impressive, enlightening and pleasant experience After a preliminary intimation the mechanism of the Society begins to reveal itself there are a faithful few who toil at necessary humble tasks—our late lamented secretary, Dr Michael A Tighe, our treasurer Dr Eliot Hubbard, our executive secretary Mr Robert St B Boyd, our editor Dr Robert N Nye with his able assistants and their stenographic staff these turn the wheels, gears and cogs of the Massachusetts Medical Society

During the past year the machinery has needed some internal adjustments In October we lost by illness the services of Miss Katharine Cowles who had long kept our clerical house in order In January we took over by previous arrangement, our own office obligations and thus ended a period of years in which we had been dependent on the staff of the *New England Journal of Medicine* for whatever bookkeeping and stenography were needed In January we were first deprived of the services of our faithful secretary though happily we thought, he was able to direct us from afar while his coronary vessels rebuilt a collateral circulation But this was not to be He was able to make a few more visits to the headquarters of the Society, and attended several committee meetings during the early spring On April 8 the day before we expected him to join us again at 8 Fenway, Dr Tighe suddenly died.

We were warned but not prepared for this. Along with his sense of humor his kindly comradeship and his interest in every ramification of the Society, Dr Tighe has taken with him a knowledge of our affairs which surpassed that of any other man These are the great losses of every organization—the contemporary intellects on which we depend, even thoughtlessly as we depend on roadways and bridges to get us about our daily work. We come to take them for granted and then they are gone. This was an irreparable loss. I ask the Society to stand for a moment of silent tribute to Secretary Michael A Tighe.

In the face of these adjustments the Society has been fortunate in its office personnel including among others Miss Margaret E Biggs, Miss Elnor Kelley and especially Mr Boyd. How confidently a troubled institution may depend on the character and fidelity of a few individuals was vividly demonstrated to those of us who were close to these changes, and were naturally anxious to have the engines working smoothly while we were taking our turn at the steering wheel.

The one hundred and sixty-sixth year of the Massachusetts Medical Society is now closing An organization which has survived over such a period of time not only

has inevitable traditions and duties to which it must respond but also finds itself inevitably watched by other groups in the larger community of which it is a part. It must solve its problems not in its own interests alone but in the interests of the people as a whole. This is peculiarly true in our profession, and it is on this account that we tend to come to our decisions slowly. Much spade work must precede the actual conclusion of most of our business, and much spade work is now quietly going on, the result of which may not become apparent for months or years to come. In giving an account of business concluded by the Society, I therefore ask you to bear in mind that none of it is the fruit of a single year of effort, but is rather the natural conclusion of processes which have been initiated and prepared in preceding years. In like manner new business has been proposed and studied during the current year which can only be reported as in progress at the present moment.

Veterans' Contract

Late in 1945 the Veterans Administration evolved a new medical policy, under Generals Bradley and Hawley. The Administration's new policy had two main objectives — the staffing of its expanding hospital facilities, which was placed upon the shoulders of the Nation's medical schools, and the provision of home and office care for all veterans by doctors of their own choosing. Early in 1946 the Veterans Administration asked the Massachusetts Medical Society to undertake the responsibility for the latter function, and a committee under the chairmanship of Dr. Humphrey L. McCarthy undertook what was to become a long and difficult task of orientation and negotiation. The Council devoted a special eight-hour meeting to the subject on April 10 and discussed it again on October 2, 1946. On October 26, agreements based on these discussions were reached with the Veterans Administration, and the matter was placed in the hands of the Blue Shield for administrative arrangements. The contract was signed and went into effect as of December 27, 1947, only to encounter the obstacle that the Blue Shield needed permissive legislation in order to carry out the contract. Opposition to such legislation has since appeared, and there have arisen other complications the details of which are not pertinent at this time. It should be emphasized here that the Massachusetts Medical Society is in no way compromised by these complications because it has sought and seeks nothing in the whole matter. The Society has merely responded and will continue to respond to every suggestion that it might be helpful to the interests of the veterans of this Commonwealth.

Director of Medical Information and Education

During 1945 several of the committees of the Society realized that it needed a more dynamic approach in its relations with the people, their legislators and their spokesmen, we were being socially misrepresented and misunderstood at a time when there was every reason for us to assert ourselves. A bill to license chiropractors reached Governor Tobin's desk, a nation-wide antivivisection effort vented itself in this state, among others, our motives in working for the establishment of the Medical Approving Authority were questioned, the call for postgraduate medical education was mounting beyond all available resources in the Commonwealth. These things led three of our committees to indicate their belief that the time had passed when the Society could depend on its committee members to meet without further aid the challenges of the day. President Fitz skillfully focused these needs for action with the result that the Council, on October 3, 1945, created a position to be known as Director of Medical Information and Education, and agreed to appoint such an officer on proposal by a special group, the Committee of Seven, named for the purpose by Dr. Fitz. Finding an incumbent worthy of so great a task proved to be a difficult matter. The Committee of Seven worked for more than a year before they finally proposed to the Council, on February 5, that Dr. John F. Conlin be named. Dr. Conlin is to begin his duties on July 1, and we bespeak for him the interest and support of every fellow of the Society.

Annual Assessment

The employment of the Director of Medical Information and Education will throw the budget of the Society out of balance. The narrow margin by which we have been able to do business in recent years has been frequently commented on, and was brought before the Council with a proposal for increasing the annual assessment three years ago. At that time and since, certain unmet obligations of the Society have been discussed. A year ago the Council ordered the appointment of a special committee to study the entire problem and to report with recommendations. This report was placed before the Council on February 5, with recommendations of far-reaching importance to the future of the Society and the medical profession in the Commonwealth.

The committee recommended in principle that the Society employ a full-time secretary, that the Society support and thereby expand the usefulness of the Boston Medical Library, that financial support be arranged for needy widows and orphans of physicians, as well as for physicians themselves, that a retirement plan be established for full-time workers of the Society and that our present inadequate headquarters be expanded to provide at least sufficient committee rooms for the proper conduct of our business. The committee recommended an increase in the annual assessment from ten dollars to between twenty and twenty-five dollars. After approving the tentative program as outlined and carefully considering its implications in future expenditure, the Council voted on February 5 that the assessment be increased from ten to twenty-five dollars, beginning on January 1, 1948. In taking this action the Council extended our horizon beyond any to which we have been accustomed. The Society can now gaze out upon a field in which literary and sociologic responsibilities are accepted along with the scientific, educational and political interests of the past. If the world is to have a future it is apparent that the Massachusetts Medical Society intends to make itself a part of it.

Postgraduate Education

Over a period of years the Society has expressed an increasing interest in postgraduate medical education. This has been largely due to the excellent work of a committee under the chairmanship of Dr. W. Richard Ohler. It has sometimes worked as a special committee and sometimes as a subcommittee under another name, such as medical defense, war participation or postwar planning. Whatever it has been called, it has done its job so well that each year our educational activities have been expanded, the high point having been reached in March and April of this year when more than 1200 doctors registered for forty-eight hours of instruction at Sanders Theater in Cambridge. Because this course alone was the equivalent of a complete college education for a score or more men we have been referring to Dr. Ohler as "President of Sanders College" and to Dr. Lewis M. Hurxthal as "Dean." Their curriculum included everything except football, and if it continues to increase in popularity they will be forced to adopt some athletic tactics in order to handle the crowds. In addition to these two there are of course scores of others who have willingly served, not only on the faculty of "Sanders College" but at the district meetings throughout the Commonwealth, at the meetings of the Postgraduate Assembly and on the programs now taking place here at the annual meeting. Altogether a formidable amount of postgraduate medical education is being provided for the doctors of Massachusetts by the fellows of the Society.

The Committee on Postgraduate Medical Education also has continued to operate the Bureau of Medical Information, which has been ably handled by Miss Mary D. Gaston at the Society Headquarters. This activity admirably met an early postwar need. What its future usefulness may be, however, is uncertain, we no longer have great numbers of medical strangers passing briefly through our midst, doctors are becoming established and tend to acquaint themselves individually with the local clinics and opportunities. The monthly cataloging of the greater Boston clinics is a helpful service, but to continue to operate the Bureau for this activity alone seems a little expensive.

The State of the Society

When I assumed the office of president a year ago, I received felicitations from a friend who pointed out that he had just completed fifty years of uninterrupted fellowship in the Massachusetts Medical Society. It occurred to me that such an event is significant in the life of any man or woman and is worthy of more than passing notice. Becoming interested I drew up a list of the fellows who were admitted to the Society in 1897, twenty two of these were still living. They had obviously passed the age at which they were entitled to retire by our bylaws, yet by consulting the records I found that eleven of them had retained continuous active fellowship over the period of fifty years. I have written to each of these eleven, hoping they could attend their fiftieth meeting. I now propose to read their names and if they are present I ask them to acknowledge that fact by rising.

Dr George A. Boucher of Brockton
Dr John E. Fish, of Canton
Dr Arthur P. George, of Haverhill
Dr Joseph B. Howland of Hingham
Dr Joseph I. Landsay of Grafton
Dr James F. Loughran, of Lowell
Dr Franklin S. Newell of Boston
Dr Ernest D. Pillsbury of Stoughton
Dr Thomas B. Shaw, of Worcester
Dr John B. Thomas, of Pittsfield
Dr William J. Walton of Dorchester

We have no official award that we can make to these gentlemen, but I extend to them the hearty congratulations of the Society and I present their names to you as tangible evidence that the state of the Society is vigorous and sound.

Dr George A. Boucher, of Brockton, was present, and acknowledged the greeting of the Society.

The President resumed the chair, and as the next order of business introduced Dr Harrison H

Shoulders, president of the American Medical Association.

Dr O'Hara then introduced the delegates who were present from the other New England state medical societies—Dr Carl T. Phillips from Connecticut, Dr George E. Young from Maine and Dr Emery T. Porter from Rhode Island. Each acknowledged this introduction, and Dr Porter spoke as follows:

Dr O'Hara if your members have been reading the papers lately they have probably seen that Governor Bradford has recently called attention to the fact that there is an old Massachusetts law which states that any body coming from Rhode Island and Providence Plantations, the home of Roger Williams is subject to death on crossing the border into Massachusetts.

So I warmed my way through the park this morning and did not get caught, and I welcome this chance to bring greetings from the State of Rhode Island where the Rhode Island Medical Society has just finished its one hundred and thirty sixth annual meeting.

The President next introduced the incoming officers, after which the one hundred and thirty-ninth annual oration, "Medical Care in Our Free Society," was delivered by Dr Leland S. McKittick. (The oration appeared in the June 19, 1947, issue of the *Journal*).

Dr O'Hara declared the one hundred and sixty-sixth annual meeting of the Massachusetts Medical Society adjourned at 1:00 p.m.

JOSEPH GARLAND, *Secretary*

APPENDIX

OFFICERS FOR 1947-1948

President Edward P. Bagg, Holyoke, 207 Elm St.
President Elect Daniel B. Reardon, Quincy, 1186 Hancock St.
Vice-President Charles J. Kickham, Brookline Office, Boston, 508 Commonwealth Ave.
Secretary Joseph Garland, Brookline Office, Boston (15) 8 Fenway
Treasurer Eliot Hubbard Jr., Cambridge, 29 Highland St.
Assistant Treasurer Norman A. Welch, West Roxbury Office, Boston, 520 Commonwealth Ave.
Orator Allen S. Johnson, Springfield, 276 Bridge St.

COMMITTEES ELECTED BY THE DISTRICTS

Executive Committee of the Council—Established 1941 (members ex-officio and one counselor and alternate elected by the councilors of each district medical society)
President—Edward P. Bagg, Holyoke, 207 Elm St.
President Elect—Daniel B. Reardon, Quincy, 1186 Hancock St.
Vice President—Charles J. Kickham, Brookline Office, Boston, 508 Commonwealth Ave.
Secretary—Joseph Garland, Brookline Office, Boston (15) 8 Fenway
Treasurer—Eliot Hubbard Jr., Cambridge, 29 Highland St.

Term Expires 1948

Essex South—Walter G. Phippen, Salem, 31 Chestnut St. (Alternate—Bernard Appel, Lynn, 281 Ocean St.)
Hampshire—Henry A. Tadgell, Belchertown Belchertown State School (Alternate—Lawrence N. Dorgan, Amherst, 66 Amity St.)
Middlesex South—Harold G. Giddings, Newton Centre Office, Boston (16) 270 Commonwealth Ave. (Alternate—Arthur M. Jackson, Everett (49) 512 Broadway)

Norfolk South—Fred A. Bartlett, Wollaston (70) 308 Beale St. (Alternate—Harry Braverman, Quincy (69) 43 School St.)
Suffolk—Alexander J. A. Campbell, Boston (15) 520 Commonwealth Ave. (Alternate—Howard F. Root, Boston (15) 81 Bay State Rd.)
Worcester—Bancroft C. Wheeler, Worcester, 27 Elm St. (Alternate—Franklyn P. Bousoquet, Worcester, 390 Main St.)

Term Expires 1949

Barnstable—Paul M. Butterfield, Harwich. (Alternate—Paul P. Henson, Hyannis, 149 Main St.)
Bristol North—Joseph L. Murphy, Taunton, 23 Cedar St. (Alternate—Curtis B. Kingsbury, Taunton, 63 Prospect St.)
Bristol South—Richard B. Butler, Fall River, 278 North Main St. (Alternate—Curtis C. Trapp, New Bedford, 416 County St.)
Essex North—Roll C. Norris, Methuen, 247 Broadway. (Alternate—George J. Connor, Haverhill, 81 Merrimack St.)
Middlesex East—Keoneth L. MacLachlan, Melrose, 1 Belle Vue Ave. (Alternate—Justin L. Anderson, Reading, 53 Woburn St.)
Plymouth—George A. Moore, Brockton, 167 Newbury St. (Alternate—John C. Angley, Bryantville, School St.)

Term Expires 1950

Berkshire—John Hughes, Pittsfield, 74 North St. (Alternate—Edward Wyman, Great Barrington, 244 Main St.)
Franklin—Lawrence R. Dame, Greenfield, 78 Federal St. (Alternate—Frank W. Dean, East Northfield, 185 Main St.)
Hampden—Archibald J. Douglas, Westfield, 80 Court St. (Alternate—Frederic Harler, Springfield, 20 Maple St.)
Middlesex North—William M. Collins, Lowell, 174 Central St. (Alternate—Artemas J. Stewart, Lowell, 310 Merrimack St.)

NORFOLK Charles J E Kickham, Jamaica Plain Office, Brookline, 1101 Beacon St. (Alternate Carl Bearse, Boston, 483 Beacon St.)

WORCESTER NORTH John J Curley, Leominster, 89 West St. (Alternate George P Keaveny, Fitchburg, 62 Fox St.)

Committee on Nominations — Established 1874 (one councilor and alternate elected yearly by each district medical society)

BARNSTABLE Paul M Butterfield, Harwich (Alternate Paul P Henson, Hyannis, 149 Main St.)

BERKSHIRE John Hughes, Pittsfield, 74 North St. (Alternate N Newall Copeland, Pittsfield, 131 North St.)

BRISTOL NORTH Joseph L Murphy, Taunton, 23 Cedar St. (Alternate Curtis B Kingsbury, Taunton, 63 Prospect St.)

BRISTOL SOUTH Henry Wardle, Fall River, 173 Purchase St. (Alternate Donald R Mills, Edgartown, Box 654)

ESSEX NORTH Charles F Warren, Amesbury, 155 Main St. (Alternate Percy J Look, Andover, 115 Main St.)

ESSEX SOUTH Peer P Johnson, Beverly, 1 Monument Square (Alternate O S Pettingill, Middleton, Essex Sanatorium)

FRANKLIN John E Moran, Greenfield, 15 Franklin St. (Alternate Warren D Thomas, Montague, Central St.)

HAMPDEN George L Schadt, Springfield, 44 Chestnut St. (Alternate George L Steele, Springfield, 20 Maple St.)

HAMPSHIRE Henry A Tadgell, Belchertown, Belchertown State School (Alternate Lawrence N Durgin, Amherst, 66 Amity St.)

MIDDLESEX EAST Edward M Halligan, Reading, 37 Salem St. (Alternate John M Wilcox, Woburn, 6 Bennett St.)

MIDDLESEX NORTH William F Ryan, Lowell, 219 Central St. (Alternate William M Collins, Lowell, 174 Central St.)

MIDDLESEX SOUTH Harold G Giddings, Newton Centre Office, Boston, 270 Commonwealth Avenue (Alternate Fred R Jouett, Cambridge, 1 Craigie St.)

NORFOLK Albert Ehrenfried, Brookline Office, Boston (15), 520 Commonwealth Ave (Alternate Carlton E Allard, Dorchester, 428 Columbia Rd)

NORFOLK SOUTH Henry A Robinson, Hingham, 205 North St. (Alternate Frederick Hinchliffe, Cohasset, 117 South Main St.)

PLYMOUTH Bradford H Peirce, South Hanson, Plymouth County Hospital (Alternate Alfred L Duncombe, Brockton, 38 Winthrop St.)

CASE 33351

PRESENTATION OF CASE

A forty-six-year-old man entered the hospital because of upper abdominal pain.

There was a life-long history of "stomach ache" three or four times a year. Six years before admission the patient suddenly and painlessly vomited over a cupful of red blood. He was put to bed and treated with Amphogel and belladonna and placed on a bland diet. From that time he began to have gnawing epigastric pain every two or three weeks, lasting one or two days at a time. The pain responded readily to milk, to sodium bicarbonate or simply to a stricter adherence to the diet. Three and a half years before admission the pain became worse and failed to respond to the medical regime. X-ray examination of the stomach was said to have shown an ulcer that was "partially blocking the outlet." An operation, probably a gastroenterostomy, was performed with complete relief for a year and a half. Ten months before admission, after a series of family misfortunes, the attacks returned. At that time they were even severer, occurring several times a week and radiating from the epigastrium to the back. Sodium bicarbonate afforded immediate relief. Six months before entry the patient had an attack of "intestinal grippe," with a pain and cramps low in the abdomen, and diarrhea without blood or mucus lasting for a week. The pain in the upper abdomen was subsequently constant, soda affording relief for only twenty minutes at a time. The patient went on a self-imposed milk and egg diet and lost 16 pounds without much benefit. He could not recall specific instances of food aggravating the pain, but had an impression that eating normal meals was deleterious. Throughout that period he never felt nauseated and had noted no change in bowel habits.

Physical examination revealed a thin patient, who complained of gnawing epigastric and back pain until relieved by milk. The heart and lungs were normal. A vertical scar occupied the midline in the epigastrium. The epigastric region was slightly tender.

The temperature was 99.5°F, the pulse 88, and the respirations 16. The blood pressure was 120 systolic, 74 diastolic.

Examination of the blood disclosed a red-cell count of 4,250,000 and a white-cell count of 14,500, with 80 per cent neutrophils. The urine was normal. The stools gave a ++ reaction for blood.

On fluoroscopic examination, the stomach was seen to be filled with a large amount of residual food. Along the lesser curve there was a large area of rigidity, with an ulcer crater 2 cm. in depth and 3 cm. in diameter within which there was a filling defect (Fig. 1). The lesser curvature, from a distance of about 2 cm. above the ulcer down to the pylorus, was rigid and shortened. Insufficient barium passed into the duodenum to fill out the duodenal bulb to a normal contour. No barium left the stomach by way of an anastomosis.

A fasting gastric aspiration failed to produce free acid, which was present after the administration of histamine, however.

The patient was kept virtually free of pain by hourly feedings. The temperature and white-cell count fell to normal. The morning gastric residual fluid was reduced from 300 to 75 cc. during the first week. On the seventeenth day gastroscopy revealed a constantly deformed and rigid-appearing angulus whose outline was irregular and slightly nodular. No peristalsis was visible. The ulceration seen at fluoroscopy was out of the range of the gastroscopist.

Three days later an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. RICHARD SCHATZKI: I shall reverse the customary procedure and start with the x-ray films. That is my usual approach to a case, although I have the history in the back of my mind while discussing the films. The record gives an adequate description of what is seen on the films. There is a crater. One thing that I cannot see but that the fluoroscopist apparently saw is the pylorus, unless it is this area, which would mean that the crater extended all the way to the pylorus. The lesion is characterized by a large crater that differs from the usual crater in that it contains a filling defect. The rigidity described in the record is not visible on the film. The shortening of the lesser as compared to the greater curvature can be seen. Another point, not mentioned in the record, is that the gastric folds converge to this crater. That does not help in differential diagnosis, however, because we have seen too many cancers with converging folds. Some of the folds reach the crater, but others do not quite reach it. That may be of significance.

The differential diagnosis, of course, is between benign and malignant ulcer. I might say that if the roentgenologist can be of any help in the differential diagnosis it is in the type of case in which he can see a tumor that has become ulcerated. The ulceration may be the leading roentgenologic sign, but by careful examination the tumor that has ulcerated and surrounded the ulcer may be demon-

strated In such a case the roentgenologist is helpful because he can make a flat-footed diagnosis of cancer There are other cases in which the lesion has the characteristic appearance of what we learned in school to be peptic ulcer of the stomach In a case like the one under discussion the roentgenologist can say that the ulcer is macroscopically benign but cannot say that the lesion is not malignant

crater This may be seen in the ulcerative infiltrating type of cancer Another reason is this peculiar defect in the crater After having looked at the defect for some time I decided that I still did not know what it was I thought of a polypoid tumor protruding into the lumen, which I cannot remember ever having seen and which I do not believe this defect represented I am certainly not able to say

FIGURE 1

nant histologically I shall not go into statistics regarding how many of these lesions turn out to be cancer on microscopical examination A third type of lesion — these are the difficult ones — occurs in cases in which the ulceration is present in an infiltrating cancer The cancer does not form a real tumor mass but merely a small, nodular irregularity around the crater In the case under discussion I cannot see anything that I should call a gross polypoid tumor that may have ulcerated Offhand, my first impression was to call this a grossly benign ulcer from the x-ray point of view There are a few disturbing facts about such a statement, one of which is that the folds do not quite reach the

whether an anastomosis was present, since none is visible One reason for its not being visible may be that the anastomosis was closed off, another possibility is that the operation three and a half years before entry was not a gastroenterostomy done on the lower pole of the stomach but a pyloroplasty In that event the appearance of the crater might have had something to do with the operative procedure There was no history of bleeding in this case to warrant the diagnosis of blood clot Food in the ulcer may give such an appearance, although the defect seems too constant to be explained on the basis of food It may be worthwhile to say a few words about the clinical record

I believe that the history alone in cases of this sort does not indicate the differential diagnosis between benign and malignant ulcers, but it increases the percentage of probability one way or the other. When I started reading the history I had no doubt that the patient had had a benign ulcer in the past, at either the pylorus or the duodenum. The course sounds typical of a classic case of ulcer. Then, in the last year, something happened. The history becomes confusing. If one did not have the first part of the record one might think that this was a case of cancer. The pain was relieved by milk. I do not know how much attention is paid these days to gastric acidity. It can certainly be said that patients with cancer may have a great deal of gastric acid and that patients with ulcer may have no acid at all, although in a large group of cases patients with ulcer have more acid than those with cancer. In a case like the one under discussion the presence or absence of acidity does not make the diagnosis, it merely changes the percentage. This man had some acid after the administration of histamine.

How does the size of the ulcer enter the picture? It does not, as a matter of fact. If there is a large crater, which appears grossly benign, the chances are that histologically it will be benign. The cases in which there is difficulty in the differential diagnosis are those of small ulcers, 1 or 2 cm. in diameter. I shall not discuss the significance of the location of the ulcer in detail and shall say only that a great many ulcerations in the prepyloric areas are cancers and that a great many are benign.

Why, in a given case, does one bother to talk about the differential diagnosis — why not remove the stomach if the treatment of gastric ulcer is definitely surgical? It is true that in practically none of these cases can histologic malignancy be ruled out, but given a lesion that looks grossly benign in a patient who is a poor operative risk, one should be more conservative in treatment. For this reason it is justifiable and essential to make the preoperative diagnosis as exact as possible. In the case in question the chances are that the lesion was grossly benign, but it may have been an ulcerated infiltrated cancer. This is not the type of ulcer that I should entrust to medical treatment.

Dr. BENJAMIN CASTLEMAN: The report of Dr. Schulz was as follows: "The appearance is that of a large gastric ulcer that has more of the criteria of a grossly benign ulcer than of a malignant one. Cancer cannot be ruled out. The area is fixed."

Dr. WELCH, have you any opinion?

Dr. CLAUDE E. WELCH: I should think that it was cancer. If you ask me why, I cannot tell you.

CLINICAL DIAGNOSIS

Gastric ulcer
Gastric carcinoma?

DR. SCHATZKI'S DIAGNOSIS

Grossly benign ulcer

ANATOMICAL DIAGNOSIS

Multiple benign peptic ulcers of stomach

PATHOLOGICAL DISCUSSION

Dr. C. J. MIXTER, JR.: This man had had a previous posterior gastroenterostomy, and at operation there was a large mass in the region of the prepyloric area that grossly appeared to be malignant. There was also evidence of an old duodenal ulcer. The duodenum was closely drawn together, so that the acute lesion was really a prepyloric ulcer. Since the lesion appeared to invade the pancreas beneath it, we thought that it was necessary to treat it as a malignant lesion and took out part of the pancreas beneath it.

Dr. CASTLEMAN: The specimen that we received showed a firm, hrawny mass in the lower third of the stomach. The fat around it seemed to be porky. When the stomach was opened the center of the mass showed an ulceration about 4 cm. in diameter. We were unable to find anything to correspond to the filling defect. One of the surgeons who saw it said that the base was flat and granular and that there had been no projections from it at the time of operation. There may have been something there when the x-ray film was taken. Just distal to the ulcer was an opening of a gastroenterostomy on the posterior wall, and there was also another ulcerating, rather shallow lesion on the lesser curvature. On microscopical examination the large ulcer was benign, with a base that was made up primarily of the serosal fat. There was practically no stomach left. The other lesion high up on the stomach was also a benign ulcer.

Dr. SCHATZKI: Do you remember how large the upper ulcer was?

Dr. CASTLEMAN: Less than 1 cm. in length and somewhat shallower in depth — I should say, from the microscopical sections, not more than 0.5 cm.

CASE 33352

PRESENTATION OF CASE

First admission. A sixty-one-year-old American-born Irish plumber was admitted to the hospital because of abdominal swelling.

About two months before admission the patient had noticed the onset of a dull abdominal discomfort centering in the epigastric and periumbilical regions. It was a steady, dull pain occurring during the morning or early afternoon and tending to persist throughout the day. It was sometimes precipitated or aggravated by food or activity. There was no particular way to relieve the pain. The patient had also noticed bloating accompanying meals, and for six weeks prior to admission the abdomen had

become increasingly swollen, causing some dyspnea. He began to be constipated a month before admission, the previous bowel habits having been regular. Laxatives had produced daily bowel movements in that period, and the urine had been dark. During the week before admission he noted that the stools were somewhat lighter. Also for several weeks prior to admission he had noticed an increase in his chronic "cigarette cough," with the production of white phlegm, occasionally flecked with blood. He denied vomiting, hematemesis or tarry stools, although at an interview in the Out Patient Department two weeks prior to admission he had admitted vomiting blood some five weeks previously and passing a dark stool. He had not been jaundiced and had had no itching. He had continued to work until a month before admission.

Ten years previously an operation had been performed for a perforated peptic ulcer, without preceding or subsequent gastrointestinal symptoms until the present illness. After the operation the patient had followed a bland diet for five months, and he was then told that he was well. For at least ten years he had been drinking a pint of whisky and six or seven glasses of beer daily. During that time the diet had been fair, with three meals a day, red meat once daily, at least one vegetable and frequently fruit, until about six months before admission, when his appetite had become rather poor and he had begun to skip meals. He had had occasional epistaxis for many years, most recently on two or three occasions after blowing the nose. Also, the ankles had been swollen for about ten years, in association with the development of varicose veins. He denied any history of rheumatic fever or swollen joints.

Physical examination disclosed a well developed, poorly nourished, ruddy-appearing man in no acute distress, with many telangiectases and spiders over the shoulders, anterior upper portion of the chest and the arms. There was questionable icterus of the scleras, and slight injection of the nasal mucosa. The tongue had smooth, red edges. The heart appeared enlarged to the left and right. The apical impulse was 10 cm to the left of the midsternal line in the fifth interspace. The apical first sound was loud and booming. The pulmonic second sound was louder than the aortic. There was a Grade II systolic, roaring murmur heard best in the third and fourth left interspaces and at the apex. The abdomen was greatly distended, with shifting dullness and a fluid wave. The liver was not enlarged to percussion, and neither the liver edge nor the spleen could be felt. External hemorrhoids were visible on rectal examination. There was a slight tremor of the hands, and Dupuytren's contractures of both hands. There was marked edema up to the mid-thigh, and moderate sacral edema. There was brown pigmentation over the lower legs bilaterally.

Examination of the blood revealed a red-cell count of 3,030,000, with 10 gm of hemoglobin, and a white-cell count of 3300, with 69 per cent neutrophils. The urine gave a ++ test for albumin and a ++ test for bile, with rare hyaline casts in the sediment. The stools were guaiac negative. The prothrombin time was 28 seconds - (control, 16 seconds). The total protein was 7.2 gm per 100 cc, with an albumin of 3.0 and a globulin of 4.2 gm (albumin-globulin ratio of 0.7), the nonprotein nitrogen was 22 mg, the cholesterol 170 mg and the vitamin A 0.0 units per 100 cc, and the cephalin-flocculation test was +++ in twenty-four and ++++ in forty-eight hours. The van den Bergh reaction was 1.4 mg per 100 cc direct and 2.2 mg indirect, and the alkaline phosphatase 2.7 units per 100 cc. The blood Hinton reaction was negative.

A gastrointestinal series revealed a small hiatus hernia at the lower end of the esophagus and varices in the esophagus above. The stomach appeared quite normal. Barium passed the pylorus without hesitation, filling the duodenal bulb, which was deformed in a manner characteristic of an old ulcer but within which no active crater could be demonstrated. Chest films showed prominence of the left ventricle and linear areas of atelectasis in both bases. There was elevation of both leaves of the diaphragm.

Mercupurin, with a high-protein, high-carbohydrate, low-fat diet, was administered, and two transfusions were given. Two and a half weeks after admission the total protein was 7.1 gm per 100 cc, with an albumin of 2.3 gm and a globulin of 2.8 gm (albumin-globulin ratio of 0.9), the prothrombin time had dropped to 20 seconds (control, 15 seconds), and the cephalin-flocculation test remained unchanged, as did the van den Bergh reaction. A paracentesis three weeks after admission yielded 8350 cc of cloudy, amber fluid with a specific gravity of 1.012. A bromsulfalein test at that time revealed 44 per cent retention of the dye. In spite of massive doses of vitamin K intravenously, the prothrombin time remained at 20 seconds against a 15-second control. It was believed that this contraindicated a liver biopsy.

A month after admission the temperature suddenly spiked to 103°F, following a shaking chill. The patient had a nosebleed that morning, and he stated that he had been getting blood out of the back of his throat for the past three days. He had a slight cough, no chest pain or dyspnea and no leg or abdominal pain. The throat was slightly injected. A chest film showed linear areas of increased density in the right lower chest. The right leaf of the diaphragm was elevated and somewhat irregular. By that night the temperature had receded, and the patient felt much better. A few days later a cephalin-flocculation test was ± in twenty-four hours and ++ in forty-eight hours, and the thymol turbidity was 5.5 units. The

icterus seemed definitely less. The hemoglobin was up to 13 gm. Ascites, however, seemed to re-accumulate rather rapidly. Five weeks after admission the patient vomited following nausea, although he had had almost nothing by mouth. He had one bowel movement of tarry, black, unformed material and seemed slightly confused, twitching frequently with gross clonic contractions of large muscle groups, but he showed no evidence of shock and the blood pressure and pulse remained steady. Subsequently, he passed two fairly large tarry stools. There was no change in the blood pressure or pulse and no hematemesis. Several transfusions were given, and the stools became brown but were still guaiac positive. There seemed to be little change in the course, and the bleeding had apparently stopped, consequently, the patient was discharged on a strict diet seven weeks after admission.

Second admission (six weeks later) During the interim the patient was followed to the Out Patient Department and apparently kept to his diet. He was given Mercupurin, and occasional paracenteses were done. After the last paracentesis he developed a dry cough and pain in the lower abdomen, especially when coughing. He had had a few small hemoptyses during the week prior to admission. He had felt badly, and his appetite had become poor. He suddenly developed a shaking chill, with a subsequent rise of temperature, and he was admitted to the hospital with a temperature of 104.5°F and a blood pressure of 148 systolic, 84 diastolic. He was treated with penicillin and within three days showed great clinical improvement with subsidence of the fever. A paracentesis was performed on the fourth hospital day, yielding 12,700 cc of deep-yellow, opalescent fluid with a specific gravity of 1.004. The patient was subsequently discharged.

Final admission (two weeks later) The patient was admitted in a slightly confused state. He stated that about a week before admission his appetite had begun to diminish and that he had started to vomit coffee-grounds material after meals. He was constipated for a week, and when he finally had a bowel movement on the day of admission the stool was copious and brown. He had observed no frank blood in the stools, which had not been clay colored. During that period he had complained of severe heartburn starting in the epigastrium and made worse by food. This pain radiated up to the anterior portion of the chest. Four days prior to admission the abdomen had become tight and swollen, and a physician had performed a paracentesis. The patient was given 4 gm of ammonium chloride daily for a week.

Physical examination was essentially unchanged. Examination of the blood revealed a red-cell count of 3,000,000, with 10 gm. of hemoglobin, and a white-cell count of 8600, with 84 per cent neutrophils, 16 per cent lymphocytes and toxic granulation of

the neutrophils. The urine was normal. The stools were guaiac negative. The carbon dioxide was 20.8 milliequiv per liter, the prothrombin time 33 seconds (control, 20 seconds), the cephalin-flocculation test + in twenty-four and ++ in forty-eight hours, and the total protein 7.0 gm per 100 cc, with 2.5 gm of albumin and 4.5 gm of globulin (an albumin-globulin ratio of 0.55). The nonprotein nitrogen was 52 mg per 100 cc., the chloride 91 milliequiv per liter, and the van den Bergh reaction 3.6 mg per 100 cc direct and 5.4 mg indirect. The patient seemed to improve temporarily, but on the tenth hospital day he began vomiting large amounts of guaiac-positive, coffee-grounds material. There was some tenderness in the epigastrium, and finally bright-red blood began to appear in the vomitus. Repeated transfusions were given, but to no avail, and the patient died after semicoma and a period of vascular collapse on the fifteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR VINCENT P. DOLE This patient presented a group of findings that are classic for cirrhosis of the liver. For this primary diagnosis we are given a history of alcoholism, symptoms of anorexia and epigastric discomfort, findings of varices, ascites and hemorrhoids indicating portal hypertension, spider angiomas, low-grade icterus and laboratory evidence of impaired liver function.

There is nothing in the history to suggest that biliary obstruction, neoplasm, infection or toxic agents damaged the liver. On the other hand, it is probable that the patient suffered from a deficient diet, since the stated intake of whiskey and beer contributed over 3000 calories a day to a person reported as appearing poorly nourished. Had this caloric intake been supplemented by an adequate diet, he would surely have been obese. The observation of smooth, red tongue edges suggests deficiency of vitamin B factors.

The findings of cardiac enlargement and murmur require separate consideration. Part of the enlargement seems to have been apparent only and due to a transverse position of the heart from a high diaphragm. Allowing for this, there was possibly sufficient dilatation of the left ventricle to cause functional mitral regurgitation. Deficiency of thiamine may have been contributory. There is also a fair possibility that the patient had coronary-artery disease, an electrocardiogram might have been of interest. In any event, there was no engorgement of the neck or arm veins and presumably no tachycardia to suggest that cardiac failure was a factor in the ascites and leg edema.

The episodes of hemoptysis and fever could have been due to pulmonary infection, collapse or infarction. Tuberculosis is an occasional complication of cirrhosis, but the x-ray films are not suggestive of that diagnosis. Sputum examinations would

nevertheless have been desirable. The best explanation appears to me that of multiple pulmonary infarctions, to which the patient was disposed by thrombosis of congested deep leg veins.

Finally, one is struck by the rather abrupt appearance of severe portal hypertension with intractable ascites and death apparently from a ruptured esophageal varix within about five days. Although such a rapid progression after onset of ascites occurs in uncomplicated cirrhosis, one is nevertheless tempted to speculate on a complicating portal-vein thrombosis. The symptoms of abdominal distress are consistent with such a diagnosis but occur quite often in cirrhosis alone.

I am unable either to establish or to exclude the diagnosis of portal-vein thrombosis and must leave a question to be asked of the pathologist.

CLINICAL DIAGNOSES

Cirrhosis of liver, alcoholic type
Rupture of esophageal varices

DR DOLE'S DIAGNOSES

Portal cirrhosis
Portal-vein thrombosis?
Multiple pulmonary infarctions

ANATOMICAL DIAGNOSES

Cirrhosis of liver, alcoholic type
Duodenal ulcer, chronic, active, with erosion into pancreaticoduodenal artery
Hemorrhage, recent, into intestines, stomach and esophagus
Esophageal varices?
Ulcerations of esophagus

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY The primary diagnosis in this case proved, as Dr Dole predicted, to be cirrhosis of the liver. The organ was atrophic, weighing only 1050 gm. Its surface was coarsely granular, the granules ranging from 1 to 3 mm in size, and it was diffusely tough and fibrous.

We found several possible sources for the attacks of gastrointestinal hemorrhage. The gross evidence of varices at the time of post-mortem examination was not impressive, but sections of the esophagus showed collapsed mucosal veins of considerably more than normal diameter. The mucosa of the esophagus, however, revealed numerous shallow

linear ulcerations ascending from the cardia of the stomach for a distance of 10 cm. The epithelial layer had been completely destroyed in many areas, exposing an extensive capillary bed, and these excoriations could have been the source of significant bleeding. Finally, the old ulcer in the duodenum had become reactivated, and there was fresh peptic ulceration. It is quite possible that hemorrhage occurred at various times from all three of these factors. At autopsy the entire gastrointestinal tract from stomach to rectum contained blood. The spleen was only slightly enlarged, weighing 300 gm. In patients with extensive hemorrhage just before death, however, the spleen often shrinks rapidly, and it is probable that it was considerably larger during life.

We found no thrombosis in the portal system. The lungs were somewhat collapsed and markedly edematous.

We believe in this laboratory that portal cirrhosis of the liver can be divided into two types. The first of these follows one or more nonfatal attacks of diffuse necrosis or so-called "atrophy." The second is seen ordinarily only in patients with a history of chronic alcoholism and coincident dietary insufficiency. The latter is very readily recognizable in its diffuse progressive stages by the combination of fatty vacuolization of the liver cells and a peculiar and characteristic form of hyaline degeneration. Both these changes, however, disappear rather quickly under the influence of a high-protein diet. In serial biopsies we have been able to show that the fat has decreased by 50 per cent within a month and has almost entirely gone within two months. Consequently, these pathognomonic signs cannot be expected in a patient who has been under medical treatment for a significant period. In such cases we must rely on other criteria for diagnosis. The best of these is the gross appearance of the organ. In cases that follow subacute atrophy the regeneration is irregular and coarsely nodular, the individual nodules frequently exceeding 1 cm in diameter and sometimes reaching 2 cm. The intervening bands of fibrous tissue are correspondingly wide and coarse. In the alcoholic type of cirrhosis, in contrast, the regeneration is much more diffuse, and the nodules are uniformly small, ranging from 1 to 4 mm in diameter. The liver of this patient was clearly the latter type.

HOUSE OF DELEGATES

THE report of the Massachusetts representatives to the June meeting of the House of Delegates of the American Medical Association, which will be presented to the Council of the Society at its October meeting, contains several matters of general interest.

In the first place, it comments on the final report of the committee to consider public relations and the liaison between the American Medical Association and the National Physicians Committee. The committee completely justified co-operation with the National Physicians Committee and recommended a change in the public-relations consultant, Rich Associates. The report was unanimously approved, and the recommendation adopted.

Secondly, the delegates report calls attention to the emphasis throughout the meeting on the importance of the general practitioner to the community and the need for helping him in every way possible. This was brought to a climax when it was voted to hold the December meetings of the House of Delegates in various cities, rather than in Chicago, and to follow each meeting with a two-day scientific exhibit arranged for the sole benefit of the general practitioner. Furthermore, the Council on Medical Education and Hospitals advised that, to promote a resolution previously adopted by the House of Delegates whereby hospitals were urged to establish general-practitioner services, one section of 'Essentials of a Registered Hospital' be revised to read, 'Staff sections, such as medicine, obstetrics, surgery, general practice and so forth, should be organized as may seem wise.' In addition, the Council stated that it did not approve of the habit of some hospitals, particularly those approved for resident training, in limiting staff appointments to physicians who are certified by one of the specialty boards, any physician, it added, who has had the training and experience approximately equivalent to that required for certification should be capable of rendering satisfactory service.

Thirdly, the report places emphasis on an address given by the Secretary of War, Robert P. Patterson. Mr. Patterson outlined briefly a bill (H.R. 3174, S. 1143) designed to promote and enhance the professional standing of the Army Medical Corps, thus placing it on a level equal to that in the best civilian practice. This bill contains the following provisions: an increase in base pay for all medical officers with less than thirty years' service, a 25 per cent increase in base and longevity pay for all officers who are certified as specialists, the appointment of outstanding medical specialists from civilian life to grades above those now permitted, the appointment of four physicians, distinguished respectively in the fields of medicine, surgery, neuropsychiatry and preventive medicine, as professors, with the rank of brigadier or major general, to supervise professional standards, educational programs and the assignment of qualified officers, and the utilization, if necessary, of civilian physi-

cians on a temporary part-time or full-time basis, without regard to Civil Service requirements. In closing, Mr. Patterson stated that the War Department would do everything within its power to establish, maintain and foster a high grade of professional attainment within the Medical Corps and requested support of the legislation and the program in general.

At the final session of the House of Delegates, Dr. R. L. Sensenich, of South Bend, Indiana, was made president-elect, and Dr. E. J. McCormick, of Toledo, Ohio, was appointed a member of the Board of Trustees. The annual meetings of the Association in 1948 and 1949 will be held in Chicago and Atlantic City, respectively.

TOXOPLASMOSIS

THE occurrence of cases of human toxoplasmosis in widely separated areas^{1, 2} and a recent report of the results of tests for neutralizing antibodies in human serums³ help to emphasize the increasing medical importance of this parasitic disease. The recognized types of toxoplasmosis include congenital encephalitis and hydrocephalus in infants, acute encephalitis in older children, acute febrile disease in adults resembling typhus or spotted fever and latent infection in adults detectable only by the presence of neutralizing antibodies in the serum. The clinical and laboratory diagnosis of such a protean disease poses an exacting problem.

One gains the impression from the published cases that the majority of infections are fatal, but several recoveries from acute infections have been reported.^{4, 5} Moreover, the detection of neutralizing antibodies in the serums of mothers giving birth to infected infants³ and also in the serums of persons in a random sample⁶ suggests a carrier stage of the infection or recovery from an acute phase of the disease.

Although the clinical signs and symptoms in acute cases of toxoplasmosis are not specific, the outstanding basic lesions in the fetus, in infants and in older children are caused by the affinity of the parasites for the central nervous system. This involvement leads to hydrocephalus, cerebral calcification, encephalitis, mental retardation, convul-

sions and chorioretinitis. In adults, the parasites are more widely scattered in the viscera. Whether or not density of parasitization in adults determines the range of intensity of the infection from latency to acute fatal disease is not known. Nevertheless, an awareness of the inherent diagnostic difficulties in the different age groups is necessary if a specific diagnosis is to be made.

The occurrence of hydrocephalus, intracerebral calcification or chorioretinitis in children should suggest the possibility of toxoplasmosis. To verify the presumptive clinical diagnosis, serologic tests are available and animal tests can be performed with biopsy material, tissues, exudates and sputum.

Two serologic tests, the neutralization⁷ and the complement-fixation⁸ test, have been devised for the detection of antibodies to *Toxoplasma*. These tests are of value in determining both acute and latent infections. The neutralization test has been used most widely for surveys and for the diagnosis of acute infections. Although evidence has been presented to show that the absence of neutralizing antibodies in the serums of patients with chorioretinitis does not rule out toxoplasmic infection,⁹ the test as used by the Minnesota Department of Health gave 163 positive reactions with serum from 761 patients.³ The heat lability of the neutralizing antibody made it necessary for the Minnesota group to use serums stored under special conditions when fresh specimens could not be obtained. In the St. Louis survey, positive results were obtained with serums from persons giving no previous history of illness identifiable as toxoplasmosis.⁶ The divergence of these results suggests some nonspecificity and this possibility should be clarified to determine whether false-positive reactions occur with sufficient frequency to nullify the value of the test. Obviously this necessitates wide application in hospital and field surveys. The complement-fixation test, as devised by Warren and Sabin, appears of value only in acute infections, for the test becomes negative after the acute stage has subsided in experimental animals.

The inoculation of animals, particularly of white mice, guinea pigs and rabbits, with material from patients is of distinct value in attempting to isolate *Toxoplasma*.¹⁰ These animals are highly susceptible

to this organism, and although suitable material for inoculation cannot always be obtained from patients, every effort should be made to isolate the organisms from patients with acute disease and with positive neutralization tests

The serologic and animal-inoculation tests serve a twofold purpose each extension of the former provides further evidence of their evaluation, and the development of toxoplasmosis in the animals serves to confirm the clinical diagnosis

In the past, identification of the parasites in tissues has been difficult, primarily because of inadequate fixation and staining and because other parasites, such as *Encephalitozoon*, *Sarcocystis* and intracellular tissue stages of *Trypanosoma cruzi* and species of *Leishmania*, bear some morphologic resemblance to *Toxoplasma*. The use of proper fixatives^{18, 19} and subsequent staining with polychrome stains yield films or sections in which *Toxoplasma* can be identified

Although the epidemiology and mode of transmission of human toxoplasmosis have not been explained, a wide variety of wild and domestic animals and birds are susceptible to spontaneous infection with species of *Toxoplasma*¹². Little is known about the specific relation of parasites from animal and human sources. Likewise, the role of animal infections as reservoirs for human infection is unknown whether the parasites are transmissible mechanically from one host to another, by contamination of food and water or by the bite of arthropod vectors

Since no drugs or antibiotics have been found that produce radical cures of acute infections due to *Toxoplasma*, chemotherapeutic studies are needed to search for a drug that will penetrate the host cells and destroy the parasites

BOOK REVIEWS

Clinical Methods of Neuro-ophthalmologic Examination. By Alfred Kestenbaum, M.D. 8th cloth 384 pp. New York: Grune and Stratton, 1946. \$6.75.

The book covers the field of clinical examination of the eye, the optic pathways and the associated muscles in a clear, orderly manner. The simple diagrams and tables are well integrated with the text. As a review of the clinical methods of ophthalmologic examination the book can be highly recommended. For the clinic it will have to be used with other texts on cases and on experimental research.

A Manual of Tomography. By M. Weinreb B.Sc., M.R.C.S. (Eng.), L.R.C.P. (Eng.), F.F.R. (Lond.), D.M.R.E. (Camb). 4, cloth 270 pp. with 397 illustrations. London: H. K. Lewis and Company Limited 1946. Sh. 45.

Whether this technique is called tomography, laminagraphy, planigraphy, strathigraphy, vertigraphy or sectography is splitting hairs over historical priorities or the mechanical principles of the equipment with which one happens to be familiar. All these are forms of body-section radiography.

In the twenty-five years since Boccage patented three methods of moving the x-ray tube and the film reciprocally and in the seventeen years since Vallebona published his work on the different principles of rotating the body of the patient on an axis between the tube and the film it is perhaps strange that, except for McDougall's seventy-three page monograph in 1940, no book dealing with the subject of body section radiography has previously appeared. In this country the method has been utilized essentially in only a few centers but abroad it has been embraced enthusiastically in many locations. Among the places where it has become most solidly established is Johannesburg whence comes the present monograph by Weinreb. It is regrettable that this pioneer volume fails ably to provide guidance to those who, given a little encouragement might share the author's enthusiasm for the subject.

The book is presented more as an atlas than as a text. The mere printing of three hundred and ninety-seven illustrations on two hundred and seventy pages, however, does not automatically make it a reference book. The author is apparently well aware of this fact, and makes excuses for

himself while he places the responsibility for coming out in print on the editor of the *Clinical Proceedings of Capetown*. The material was evidently gathered together for a lecture given by the author in Capetown in 1944. The text, he admits, has been "cut too severely."

Nevertheless, the book establishes many of the good points of body-section radiography. In the chest field, the technic is seen to be particularly useful in delineating the bronchial tree without the introduction of iodized oil, in discovering cavitations within consolidated pulmonary tissue and in revealing details following thoracoplasty. It may be useful in determining heart sizes in cases in which the cardiac apex is obscured on conventional films by pleurisy or by an epicardial fat pad. Some portions of the spinal column are difficult to visualize on ordinary films, but even the cervico-thoracic region, the lumbosacral articulations, the odontoid process and the atlanto-occipital joints may be shown in good detail on body-section films. Details of congenital scolioses, hemivertebrae, fusions, spondylolyses and fractures may also be revealed. In the skull the method is particularly useful for delineating depressed fractures, the auditory canals, facial fractures and the temporomandibular joints. As extra embellishments, the author has used body-section radiography to outline the aorta in angiocardigrams, to observe the process of healing of fractures of the vertebral bodies, to distinguish traumatic Schmorl's nodes from those associated with adolescent kyphosis and to visualize excretory urograms in infants whose kidneys are obscured by intestinal gas.

For reference, the book is difficult to use because of the absence of an orderly sequence in its material. Only the briefest sketch of the historical development of the subject is included. A short chapter deals with the technic of filming various parts of the body, but one will search in vain for any mention of the mechanical principles involved in the apparatus. The book's most serious defect, however, is in the quality of reproductions, many of which are so poor as to put a considerable stretch on the imagination of the reader, prompted though he is by the captions.

Surgical Treatment of the Soft Tissues. Edited by Frederic W. Bancroft, M.D., and George H. Humphreys, II, M.D., Sc.D. Philadelphia: J. B. Lippincott Company, 1946. \$15.00.

This book, which is an accompanying volume to *The Surgery of the Motor Skeletal System*, discusses injuries and deformities of the soft tissues. Hernia, superficial injuries, thermal injuries, infections, superficial neoplasms and circulatory disturbances are described by recognized authorities in these fields. The book is profusely illustrated, and each chapter has a well chosen up-to-date bibliography. This is a worthy addition to the previous volumes of this set.

NOTICES

METROPOLITAN STATE HOSPITAL

The Thirteenth Postgraduate Seminar in Neurology and Psychiatry will begin on Friday, October 10. The program will be as follows: a review course in basic neurology and psychiatry, consisting of eighty-one lectures, to be held every Friday from 2:00 to 10:00 p.m. from October 10 to December 12, 1947, and from January 2 to April 23, 1948, at the Metropolitan State Hospital, 475 Trapelo Road, Waltham; a course in social and special psychiatry, consisting of thirty-six lectures, to be held every Wednesday from 5:30 to 10:00 p.m. from October 15 to December 10, 1947, and from March 17 to May 12, 1948, at the Boston Psychopathic Hospital, 74 Fenwood Road, Boston; and a course in pediatric neuropsychiatry (child psychiatry), consisting of twenty lectures, the first two to be held on Tuesday, October 14 and 28, 1947, from 5:30 to 10:00 p.m. The remaining lectures of the course will be held on alternate Mondays from November 10 to December 8, 1947, and from March 15 to May 10, 1948, at the Walter E. Fernald State School, Waverley.

The seminar is open to all graduate physicians, but the number of vacancies for demonstrations in the review course in basic neurology and psychiatry will be limited to twenty-five in each of the subjects of the course: neuroanatomy, neuropathology and neurophysiology. If the number of applicants exceeds the available teaching facilities, preference will be given to physicians of the Department of Mental

Health and of Veterans Administration hospitals and those preparing for board examinations. Those interested are requested to apply in writing before October 6 to I. William C. Gacbler, superintendent, Metropolitan State Hospital, Waltham.

NEW ENGLAND SOCIETY OF ANESTHESIOLOGISTS

The first regular meeting of the New England Society of Anesthesiologists will be held in the Bigelow Amphitheater of the White Surgical Building, Massachusetts General Hospital, on Tuesday, September 16, at 8 p.m. The program will be as follows:

Operative Morbidity: A dual responsibility. Dr. Mel Saklad, director of anesthesia, Rhode Island Hospital.
Report of Anesthesia Study Commission of the New England Society of Anesthesiologists.

NEW YORK ACADEMY OF SCIENCES

The list of speakers at the conference entitled "Antihistaminic Agents in Allergy," which will be held at the New York Academy of Sciences on October 3 and 4, is as follows: Sir Henry H. Dale, formerly director of the National Institute for Medical Research, Mount Vernon House, England; Dr. Carl A. Dragstedt, professor of pharmacology, Northwestern University Medical School, Chicago; Dr. M. Rocha e Silva, professor of pharmacology and biochemistry, Instituto Biologica, Sao Paulo, Brazil; Dr. M. W. Chase, Rockefeller Institute, New York City; Dr. E. T. Waters, Banting and Best Department of Medical Research and Department of Physiology, University of Toronto, Toronto; Dr. N. Fell, Camp Detrick, Frederick, Maryland; Dr. D. Bovet, professor of pharmacology, University of Rome; Dr. Rudolf L. Mayer, Division of Research, Ciba Pharmaceutical Products, Incorporated, Summit, New Jersey; Dr. Earl R. Loew, Department of Pharmacology, University of Illinois College of Medicine, Chicago; Dr. Rolf Meier, medical director, Ciba Limited, Basel, Switzerland, and professor of pharmacology and therapeutics, University of Basel; Dr. Charles F. Code, Mayo Foundation, Rochester, Minnesota; and Dr. Samuel M. Feinberg, Department of Allergy, Northwestern University Medical School, Chicago.

Persons desiring to attend the conference may do so by making a request in writing to the executive secretary, Eunice Thomas Miner, Central Park West at Seventy-ninth Street, New York 24, N.Y.

NEW YORK ACADEMY OF MEDICINE

The Twentieth Graduate Fortnight of the New York Academy of Medicine will be held October 6 through October 17, the subject being "Disorders of Metabolism and the Endocrine Glands." The program includes morning panel discussions, afternoon clinics, evening lectures, scientific exhibits and demonstrations. Complete programs will be mailed to physicians on request.

A physician who is not a fellow of the Academy may obtain registration by sending his name and address, accompanied by a check for five dollars, to the Secretary of the Graduate Fortnight Committee, 2 East 103rd Street, New York 29, New York.

BACTERIAL ENDOCARDITIS

Experiences with Penicillin Therapy at the Massachusetts General Hospital, 1944-1946

OGLESBY PAUL, M.D.,* EDWARD F. BLAND, M.D.,† AND PAUL D. WHITE, M.D.‡

BOSTON

PENICILLIN was first used in the treatment of a case of bacterial endocarditis at the Massachusetts General Hospital in 1944. During the subsequent three-year period 44 patients have received this antibiotic agent with remarkable results, which are to date comparable to those reported from other large clinics. In our series 29 lives that undoubtedly would have been lost only a few years ago have been saved. On the other side of the picture, penicillin treatment is not without its technical difficulties. Attainment of cure is a lengthy and expensive process, often interrupted by unforeseen and at times tragic complications, and an over-all mortality of 20 to 30 per cent still exists. The following review of our recent experience is nevertheless heartening, and we are hopeful that with the passage of another few years the results will be even better.

It has been only recently that unlimited amounts of penicillin have been available, and some of the earlier failures might have been cured today. It should also be pointed out that these patients were treated by various persons both on the general hospital wards and in the private units and that in the beginning no common policy was established regarding dosage, route of administration and duration of treatment. Perhaps this lack of uniformity was of value in giving a broad range of experience, and the present program of therapy has evolved largely as a result of these earlier successes and failures. The methods now employed are outlined below.

CLINICAL DATA

Criteria for inclusion. No case was included unless, in addition to the clinical diagnosis of bacterial endocarditis, a minimum of three blood-

culture flasks were positive for the same organism, or unless the presence of bacterial endocarditis was confirmed at autopsy. Otherwise, no selection of cases was employed, all patients who received penicillin treatment being included, even though such treatment was limited to a few days.

It will be noted that the inclusive term "bacterial endocarditis"—rather than subacute and acute bacterial endocarditis—is employed throughout this paper. Although the vast majority of our cases were typically subacute in type, there were several with a clinical course that might be labeled either subacute or acute. We have therefore preferred to group all our cases under the general heading indicated above.

Age. The youngest patient was three and a half and the oldest seventy-two years old. Table 1 presents the number of cases in each age group. It is of interest that the youngest patient and both of those in the eighth decade did well. Age in itself does not seem to be a deterrent to successful treatment.

Sex. Twenty-four patients (55 per cent) were males, and 20 (45 per cent) were females.

Occupation. Eleven patients belonged to the white-collar group, 10 led moderately active laboring or outdoor lives, 9 were housewives, 5 were students, and in 9 cases there was no definite employment in the period immediately prior to illness.

Types of heart disease. Rheumatic heart disease predominated, with emphasis on aortic-valve lesions, as compared with the usual high incidence of mitral-valve lesions in uncomplicated rheumatic cases (Table 2). Thirty-six cases (82 per cent) fell into the rheumatic group, there was combined aortic and mitral disease in 13 patients, apparently pure aortic disease in 6, and valvular disease was considered to be limited to the mitral valve in 17. In addition, 1 patient had calcareous aortic stenosis, 1 had aortic-valve disease, unclassified, and 6 (14 per cent of the total) had congenital heart disease. The last group included 2 patients with the tetralogy of Fallot, 1 with pulmonic stenosis, 1 with subaortic stenosis, 1 with a ventricular septal defect and 1 with a patent ductus arteriosus as well as an

*Assistant in medicine, Harvard Medical School clinical fellow in medicine, Massachusetts General Hospital.

†Instructor in medicine, Harvard Medical School associate physician Massachusetts General Hospital.

‡Professor of clinical medicine, Harvard Medical School physician Massachusetts General Hospital.

An example of this was a forty-five-year-old man who was seen by one of us (P. D. W.) in February 1944. The history and physical findings were consistent with the diagnosis of subacute bacterial endocarditis, but on blood culture the results were variable and inconclusive (therefore the patient is not included in our series). A brief course of 285,000 units of penicillin, which was all the drug obtainable, produced a brief and dramatic response, but the patient died a month later from the effects of cerebral embolism.

aortic-valve lesion (? bicuspid valve, ? rheumatic involvement) A past history of rheumatic fever was obtained in 17 of the 36 rheumatic cases

Sources of infection The probable sources of infection are indicated in Table 3 In 19 patients (43 per cent) no convincing data were available The next largest group of cases (30 per cent) fol-

lowed a variety of upper respiratory infections, including the common cold, influenza, grippe, sinusitis and sore throat Dental extractions without prophylactic chemotherapy were implicated as the initiating event in 5 patients (11 per cent) There were 3 patients whose illness had begun with acute gastroenteritis, whether or not such episodes

Auricular fibrillation	3	7

101 and 102°F or higher Forty cases (91 per cent) were in this group Other symptoms in the order of incidence were weakness, weight loss (16 patients had lost 10 pounds or more), sweats or chills, or both, anorexia, rash or "spots" and joint pains (Table 4) Nine months was the longest period of

recognized illness prior to admission, over 90 per cent of patients having had complaints for six months or less

Physical findings Significant murmurs were apparent at the time of admission in 100 per cent of cases, constituting the only physical finding present in all patients in this series. Splenomegaly was next in frequency, being noted in 18 cases (41 per cent). Less common were pallor, petechiae, clubbing, signs of congestive failure and cardiac arrhythmias (Table 5).

The incidence of auricular fibrillation and flutter is of interest, since such arrhythmias are relatively infrequent in bacterial endocarditis. Three patients showed auricular fibrillation on admission, electrocardiographic proof being obtained in each case. In an additional patient auricular flutter was present in the electrocardiogram taken one day after admission, flutter and fibrillation being found on a second tracing two days later. Transient auricular fibrillation, which occurred during the treatment of another case, was also demonstrated by the electrocardiogram. Four additional patients developed gross arrhythmia during hospitalization, and in each case the clinical diagnosis of auricular fibrillation was made but no tracings were obtained. A total of 5 cases (11 per cent) thus had proved auricular fibrillation or flutter, and in 3 of these the arrhythmia had persisted throughout the entire hospital course.

Major embolic phenomena Splenic infarction, considered to be present in 7 cases, was manifested by moderate to severe pain in the left upper quadrant coming on abruptly and associated with the appearance of tenderness and often spasm, with or without a palpable spleen. Two of these patients died, and splenic infarction was found at post-mortem examination. One of the latter was associated with infarction and abscess formation ending in a fatal rupture of the spleen (this remarkable finding has been reported elsewhere^{1, 2}). In 2 other cases the existence of healed splenic infarction was demonstrated at autopsy, although no clinic evidence had been noted.

Cerebral phenomena (presumably embolic) were observed clinically in 7 patients and ranged from episodes of transient confusion, disorientation and aphasia to frank hemiplegias. Three of these patients are now living without evident residual cerebral damage, and 4 have died (1 of a recurrence of endocarditis seventeen months later). An autopsy in 1 of these cases showed a right cerebellar infarct. A diagnosis of cerebral embolism was made in another patient four days before death but was not substantiated by the post-mortem findings.

In 1 patient the appearance of gross hematuria with subsequent left-flank tenderness and spasm was considered clinical evidence of renal infarction. This condition was found at autopsy in another patient although it had not been suspected, and

similarly renal infarction with embolic nephritis and embolic nephritis alone were each discovered once by the pathologist.

Subarachnoid and intracerebral hemorrhage resulting from the rupture of a mycotic aneurysm took place in 2 cases. This occurred on the tenth day of treatment of a thirty-nine-year-old male office worker, who suddenly complained of severe headache and shortly lapsed into coma. Lumbar puncture revealed grossly bloody fluid. Despite the ominous significance of this complication, he survived for another two and a half weeks, finally succumbing to congestive heart failure. At autopsy, in addition to subarachnoid and intracerebral hemorrhage, it was found that rupture of a chorda tendinea of one leaf of the mitral valve had taken place. The other patient had just finished a four weeks' course of therapy, with apparently excellent results, when she suffered a massive subarachnoid and intracerebral hemorrhage and died within a few hours. Post-mortem bacteriologic studies, including careful culture of the involved aortic valve, which had been removed under sterile precautions and ground up, and culture of the heart's blood, were all negative. Samples from twelve blood-culture flasks had also been reported as negative during the period of penicillin treatment. It is believed that the mycotic aneurysm found at autopsy had been sterilized but that death had occurred from the resulting weakness in the arterial wall, with eventual rupture and fatal hemorrhage.³

Frank congestive failure, which occurred during the period of hospitalization of 7 patients, was related in at least 1 to the administration of too much physiologic saline solution with the penicillin. A diagnosis of active rheumatic fever was made in 2 cases.

Blood studies A hemoglobin level of less than 12 gm. per 100 cc. or a red-cell count of less than 4,000,000 was present in 68 per cent of cases, and the initial white-cell count was over 10,000 in 55 per cent. The admission blood smear showed 80 per cent or more neutrophils in 36 per cent of patients.

BACTERIOLOGIC DATA

Bacteriology Table 6 lists the organisms isolated in the 44 cases. It will be noted that no organism was obtained in 1 case—that of a gravely ill fifty-one-year-old man who died after four and a half days of penicillin treatment and in whom the diagnosis was confirmed by post-mortem examination, typical vegetations being present on the aortic valve. The case was medicolegal, and no post-mortem bacteriologic studies were done.

As would be anticipated, the alpha-hemolytic streptococcus was the organism most frequently found, accounting for 82 per cent of the series. Mixed alpha-hemolytic and beta-hemolytic streptococcal infections occurred in 2 cases, beta-hemolytic

and gamma-type streptococci were each responsible in 1, and *Staphylococcus albus* in 2. It is of interest that both cases with staphylococcal infection responded satisfactorily to treatment.

Sensitivity determinations In 31 cases data on the bacterial sensitivity to penicillin are available. These figures are presented in Table 7 (in cases in which more than one determination was made and a change in sensitivity reported, we have recorded

TABLE 6 *Organisms Obtained by Blood Culture*

ORGANISM	NO OF CASES	PERCENTAGE

the greatest rather than the least resistance to penicillin in vitro). Fortunately, the bulk of the strains isolated were inhibited in the test tube by reasonable levels of the drug, but five of them grew in a medium containing 1 or more units per cubic centimeter. The most resistant case required 8 units of penicillin per cubic centimeter of broth to inhibit growth.

Definite increases in the resistance of the organisms to penicillin were noted in 2 cases. In 1, a tenfold rise was reported, and in the other, the resistance increased one hundred and thirty times.

The significance of such information and its value in guiding treatment are not entirely clear. On the

daily, was infected with a strain of the alpha-hemolytic streptococcus for which a level of 6 units was necessary. In no case in which the sensitivity was high did failure result clearly from inability to sterilize the blood stream. On the other hand, one strain of the alpha-hemolytic streptococcus that was reported to require 25 units of penicillin per cubic centimeter of broth to inhibit growth was successfully treated with relatively small doses (192,000 units daily for nineteen days). The patient died while visiting in another city six months after discharge, having had no symptoms suggesting a return of infection and with repeatedly negative blood cultures throughout that period. The cause of death is not definitely known, although it was stated that the patient died from heart failure. It is possible that the sensitivity report was in error. In another case blood levels four to eighteen times those indicated in the test tube as being effective were maintained without evidence of sterilization of the blood stream.

It is clear that such bacteriologic procedures must be carefully performed if technical sources of error are to be eliminated and if accuracy is to be obtained. In these studies it is unfortunate that more individual technical attention was not available. The duration of chemotherapy, the manner of administration of the drug and the patient's own immune response, not to mention the anatomic features of the valvular lesion itself, must be considered before one relies too heavily on evidence in vitro, valuable though that evidence may be.

THERAPY

Routes of administration Considerable variation in the manner of administration of penicillin is found on analysis of these 44 cases. The methods employed included intermittent intramuscular injections at intervals of one, two, three and four hours, intramuscular injections of penicillin in oil and wax three times daily, constant intramuscular and intravenous drips and oral ingestion of the drug. No final conclusions regarding the efficacy of any one method can be drawn from the data at hand without a careful correlation with the dosage, resistance of the organism and blood levels obtained. Unfortunately, the information available does not lend itself to such an analysis. Isolated observations are of interest, however—for example, the facts that 1 case was satisfactorily treated solely by the oral route (in amounts of 100,000 units of penicillin every two hours) and that another patient did well after a course of only 33,000 units every four hours intramuscularly for three weeks. The results of penicillin in peanut-oil and beeswax have been reported elsewhere,^{1,2} but it was notable that at autopsy after a month of such administration there were large gluteal abscesses at the sites of injection, with extensive muscle necrosis. Cultures obtained from the abscesses revealed the same

TABLE 7 *Bacterial Sensitivity to Penicillin in Vitro*

whole, determinations of bacterial sensitivity have been found a reliable and useful method of detecting patients in whom unusually large doses of penicillin will be required if cure is to be obtained. The correlation with clinical observations is fairly satisfactory. For example, the 2 patients who remained extremely ill and whose blood cultures continued persistently positive despite doses of 8,000,000 and 15,000,000 units a day, respectively, harbored organisms with a high resistance in vitro, requiring respectively 6 and 8 units of penicillin per cubic centimeter of broth to inhibit growth. Another patient, who was finally cured by 10,000,000 units

organism that had been isolated from the patient's blood stream (the alpha-hemolytic streptococcus)

When massive doses of penicillin are not employed, the constant intramuscular drip (in the anterior thigh muscles) has been well tolerated, and the patients themselves have found it to be more comfortable than the other parenteral methods. If a satisfactory aseptic technic is employed at the time of changing the needles and if the site of injection is changed every three or four days, the risk of local abscess formation is minimal. In 5 cases so treated no difficulty was encountered (Four of these were thus treated over a period of one month, and 1 for two weeks.) In 2 additional patients who received massive doses of the drug mild local infection, which occurred after three and six weeks of constant intramuscular administration, was clearly due in 1 to gross abuse of the dressing on the part of the patient, who regularly pulled out the needle unless restrained, and in the other possibly to faulty technic. This route becomes painful if too large a volume of solution is used (we limit the amount to 800 to 1000 cc daily), if the concentration of penicillin is high (unless 0.1 per cent procaine hydrochloride is added) or if little muscle tissue is available. In certain cases other routes, such as constant intravenous and two-hourly intermittent intramuscular injections, are advisable.

It has been our experience that satisfactory blood levels are maintained with the constant intramuscular method. We have not, however, routinely determined the penicillin blood levels in the same patient, comparing constant intramuscular and constant intravenous drips. Loewe⁴ has found the latter method to give higher blood levels than the former. We are at present investigating this aspect of the problem. We have also found that the use of physiologic saline solution as the vehicle for dissolving the drug is at times hazardous when the cardiac reserve is limited, and we prefer in such cases to employ 5 per cent glucose in distilled water.

Dosage and duration. The smallest amount of penicillin that resulted in cure was 2,685,000 units, given in a short course (fifteen days), mainly by intravenous drip. The largest amount employed was 442,000,000 units, given over three hundred and fourteen days by varying routes (finally by hourly intramuscular injections totaling 10,000,000 units daily for seven days, followed by forty-two days of 5,000,000 units daily by intravenous drip). In retrospect, had large supplies of the drug been available, it would have been cheaper and more satisfactory to have resorted to massive doses much earlier in this patient. Between these extremes fall the bulk of the recovered patients, who, on the average, were successfully treated with a three-week course of 500,000 units a day.

Since the individual patient is not necessarily an "average case," careful bacteriologic control is con-

sidered essential to ascertaining the optimal dose of the drug. An amount of penicillin that will maintain a blood level at least five times that indicated *in vitro* is regarded as being necessary to inhibit growth of the organism. Should positive blood cultures appear despite achievement of this goal, larger doses should be employed. Once a satisfactory daily dose has been established, we now recommend a full four weeks' course, the therapy being halted arbitrarily at the end of that time to evaluate the situation. We have not infrequently observed a low-grade fever to persist throughout the entire course of penicillin therapy, regardless of the method of administration, only to disappear completely once treatment has been stopped. The presence of mild fever is not in itself a guide to success or failure under these conditions.

Other methods. When difficulty was encountered in controlling the infection with penicillin alone, additional measures were employed. Sulfadiazine was given to 12 patients for varying periods, and sulfathiazole and sulfamerazine each were tried once. In 9 patients benzoic acid was administered in an effort to elevate the penicillin blood level, and 1 patient received ten typhoid-vaccine chills. There was no clear evidence that any of these measures were of significance in the final results.

A ten-day course of streptomycin (in doses of 4 gm daily) was without effect in a sixty-one-year-old man infected with alpha-hemolytic streptococci, even though the organism was moderately sensitive *in vitro*. We have also recently treated a thirty-two-year-old housewife (who is not included in this series) whose blood cultures grew out *Haemophilus parainfluenzae* with great difficulty.⁵ She had been ill for sixteen months, although with minimal symptoms when treatment was instituted, had rheumatic heart disease with aortic and mitral involvement and had been unsuccessfully treated with penicillin elsewhere and by us. She developed a severe papular dermatitis accompanied by a high temperature at the end of the first week of streptomycin therapy but responded satisfactorily to Benadryl and Pyribenzamine. Treatment was continued over the course of seventeen days notwithstanding this complication and the subsequent appearance of labyrinthitis, and although the follow-up period is as yet brief, cure seems to have been achieved.

Transfusions were given to 15 patients. Ligation of a patent ductus arteriosus was performed in 1 case, supported by penicillin therapy, and the patient is well ten months later. Anticoagulants were not employed, owing to our belief that satisfactory results can be achieved without them and that an appreciable hazard accompanies their use. We have had several patients (as noted previously) who have survived cerebrovascular accidents occurring during treatment, we suspect that these pa-

tients might not now be alive if the clotting time had been prolonged at the time of these episodes

RESULTS

The results are indicated in Table 8. It will be seen that 29 patients are now alive, making a survival rate of 66 per cent.

Of the 15 fatal cases, 2 can clearly be classed as complete therapeutic failures (one critically ill patient failed to respond both to 15,000,000 units of penicillin and 4 gm of streptomycin a day, and in the other case therapy was given up after

TABLE 8 *Results of Penicillin Treatment in 44 Cases*

RESULT	NO OF CASES	PER-CENTAGE
Patient living without evidence of infection	29	66
Death from recurrence seventeen months after discharge	1	2
Death with infection apparently eliminated	6	14
From pulmonary embolism ten days after penicillin was stopped	1	
From subarachnoid hemorrhage due to ruptured sterile mycotic aneurysm five days after penicillin therapy was stopped	1	
From congestive failure one, four and seven and a half months, respectively after discharge	3	
From underlying heart disease six months after discharge	1	
Death with infection probably eliminated	2	5
From cerebral embolism during treatment with all blood cultures negative after penicillin treatment began	1

From congestive failure after only two and four and a half days of penicillin therapy, respectively	2	
From ruptured spleen after twenty five days of penicillin therapy	1	
From ruptured mycotic aneurysm and congestive failure after twenty-nine days of penicillin therapy	1	
After massive doses of penicillin had completely failed to control the infection	2	

8,000,000 units daily had been ineffective at a time when penicillin was still scarce)

Six other patients succumbed during the course of treatment. In 2 of these chemotherapy had just been started, whereas the remaining 4 died from complications of their disease before the administration of penicillin had been stopped. Two additional patients died from pulmonary embolism (clinical diagnosis) and a subarachnoid hemorrhage, respectively, after the cessation of penicillin. In both cases all blood cultures after the institution of chemotherapy had been negative, and, in addition, at post-mortem examination in 1 the heart blood and ground-up aortic valve were normal on culture.

Five other patients died after discharge from the hospital. Four of these died of cardiac conditions (3 from congestive failure, and 1 of causes not clearly ascertained) without clinical or laboratory evidence of bacterial endocarditis. All had been followed with repeatedly negative blood . . . Another patient died at another hospital sev-

months after discharge, of a recurrence of the disease, having been entirely free of evidence of active infection during the intervening period.

Follow-up data We have been able to obtain information regarding the recent status of all 29 living patients. One of these cases although a penicillin cure, should probably not be credited to us, since blood cultures taken in a distant city two months after discharge from our care were again positive for streptococci. The patient was retreated twice by a physician with large doses of penicillin, and a recent report states that he is in excellent health and is attending college. It is assumed that the original infection had never been cured, despite negative blood cultures in the immediate convalescent period. Of the remaining 28 survivors, 3 have been followed for less than six months, 7 for six months to one year, 8 for twelve to eighteen months, 4 for eighteen to twenty-four months, and 6 for two years or more. The lives of 6 of these patients are definitely restricted by cardiac disability.

SUMMARY

Forty-four patients with bacterial endocarditis received penicillin at the Massachusetts General Hospital in the three-year period 1944-1946. Twenty-nine (66 per cent) are living and are considered cured.

One patient died from a second attack of bacterial endocarditis, and 8 others succumbed to cardiovascular complications of the disease, although the infection itself appeared to have been overcome. Six patients died without evidence of control of the bacteremia.

Rheumatic heart disease was present in 82 per cent of cases in the series, 14 per cent were diagnosed as having congenital heart disease, 1 case (2 per cent) was classified as having calcareous aortic stenosis, and in another case (2 per cent) the nature of the underlying cardiac lesion was unknown.

Upper respiratory infections preceded the endocarditis in 30 per cent of cases, and extractions of teeth in 11 per cent.

Alpha-hemolytic streptococci were responsible for 82 per cent of the infections.

There were 5 cases of marked bacterial resistance to penicillin in vitro, 2 of these patients were cured.

DIAGNOSIS AND MANAGEMENT OF RENAL-ARTERY THROMBOSIS*

Report of a Case

WILLIAM E. GOODYEAR, M.D.,† AND DONALD E. BEARD, M.D.‡

ATLANTA, GEORGIA

THROMBOSIS of the renal artery is not a frequent condition, but it is not nearly so rare as is indicated by the number of times it is diagnosed. Practically all the cases reported are those found at autopsy or operation, but it is often possible to make an accurate diagnosis with present methods and with the condition in mind as a possibility.

Renal-artery thrombosis is not synonymous with renal infarction, for the latter is probably much more frequently caused by venous thrombosis, which is due to various inflammatory and traumatic lesions affecting the renal veins. Also, multiple small renal infarctions are a common autopsy finding when they were of little clinical significance in the patient's life. This paper does not propose to consider these venous or small arteriolar occlusions, it is concerned with thrombosis of the renal artery or its major branches.

This condition, when seen clinically, is usually confused with acute surgical diseases of the urinary tract or of the intra-abdominal organs, or with a medical emergency arising from acute disease of cardiorespiratory origin. The patient may be subjected to needless operation, or much time may be lost, with attention centered elsewhere from the true site of the disease.

The purpose of this paper is to present a case of definite ante-mortem diagnosis, with a review of the salient features that should be of value to others in the recognition of the condition. It is maintained that renal-artery thrombosis is one manifestation of general atheromatous vascular disease and may be diagnosed by history, physical examination, laboratory findings and urologic examination. Probably the most important single factor in diagnosis is its inclusion in the mind of the examiner as a clinical possibility.

DIAGNOSIS

The presenting symptom of renal-artery occlusion is pain. Unfortunately, this pain is not a characteristic or typical one—the only consistent feature is that it is rather severe. The onset is usually sudden, but one may be misled by a more gradual onset in which the maximum intensity is reached only after several hours.

In most cases the site of the pain is the general region of the disease, which means the flank or the hypochondrium. Either dorsal or ventral pain may predominate, and in such cases the examiner may suspect disorders of the urinary or digestive tract. The pain may go through and through, or may radiate to the lower quadrant or to the chest. It is rather constant—not colicky—and is described as both sharp and dull.

When the radiation is to the chest, the pain may simulate that of coronary thrombosis. Two such reports have been presented by Wolffe¹ and White.² Also, with pain in this region, pneumonia and pleuritis must be excluded.

Urinary symptoms are said to be present in only a small percentage of cases. The condition does not strongly suggest ureteral colic, but, of course, the two diseases cannot definitely be distinguished by history. Hematuria and hemoglobinuria, if present, more probably come from partial infarction or infarction due to venous occlusion, in which there is marked renal congestion, as opposed to renal-artery occlusion, in which there is a complete anemia.

Gastrointestinal symptoms are frequent and consist of nausea and vomiting. These, along with upper abdominal pain, may easily direct attention to the digestive tract exclusively.

A careful past history is of utmost importance, with particular emphasis on the cardiovascular, digestive and urinary systems.

The general appearance of the patient is that of acute illness. The temperature is usually slightly elevated, and may be as high as 102°F. The blood pressure and pulse are usually not directly affected by the condition, but are significant in the evaluation of the general cardiovascular status. Vascular disease is the primary cause of the condition, and a major clue may be detected by the taking of the patient's pulse.

The physical findings at the site of the pain are variable. There is usually tenderness, but marked tenderness may be accompanied by absolutely no rigidity. Muscle spasm, when present, is of the voluntary type—not that of peritoneal irritation. Abdominal distention is common. Peristalsis is usually normal, but the pain is rarely sufficient to silence it with a paralytic ileus. Pelvic and rectal examination are noncontributory.

Careful attention must be given to the cardiovascular system. In addition to the history, and

*From the Department of Urology, Emory University School of Medicine and Grady Memorial Hospital.

†Assistant resident in urology, Emory University School of Medicine and Grady Memorial Hospital.

‡Resident in urology, Emory University School of Medicine and Grady Memorial Hospital.

physical examination, an electrocardiogram should be obtained. Arteriosclerosis, hypertension and cardiac disorders as manifested by enlargement, murmurs and arrhythmias are the veritable basis for a renal vascular accident. Indeed, renal-artery thrombosis is only a part of generalized atheroma-

The most important single factor in the diagnosis is a urologic examination, by cystoscopy and ureteral catheterization and pyelography. In cases of complete occlusion of the renal artery, there is absence of urine on the side involved, with a failure of the kidney to excrete dye such as phenolsulfonephthalein or indigocarmine. This is further confirmed by failure to excrete Diodrast in an excretory urogram. Retrograde pyelography early in the disease shows an anatomically normal kidney. This is the actual finding on which the diagnosis is based—an anatomically normal kidney that has no function. Wolffe¹ states that in cases of occlusion of a major branch of the renal artery affecting approximately

FIGURE 1 *Right Retrograde Pyelogram Taken on the Day of Admission*

The kidney appears to be normal anatomically

tous vascular disease, and this fact cannot be too strongly emphasized. In the case presented below, the patient had had a previous cerebral thrombosis and finally died of myocardial infarction, showing the generalized involvement of the arterial system. The renal-artery thrombosis may strike first, however, and with abdominal pain and digestive symptoms predominating, it may be more difficult to make a prompt and accurate diagnosis.

Leukocytosis is usually present. The urine may be normal, but is likelier to have albumin, a low specific gravity and the changes found in cardiovascular renal disease. Hematuria is occasionally observed, as mentioned above. There may be elevation of the nonprotein nitrogen if the other kidney is diseased and cannot assume the entire excretory function.

FIGURE 2 *Retrograde Pyelogram Taken One Week after Admission*

There is diminution in the size of the right kidney

half the kidney the diagnosis is best shown by excretory urograms. The infarcted portion of the kidney is poorly demonstrated by the fact of no concentration of the dye in the tubules of that portion, and the pyelogram is hazy and indistinct in that pole. Our opinion is that this finding is more conclusive late in the condition rather than early, for at first the configuration of the renal pelvis is not changed anatomically. Serial pyelography demonstrates a progressive atrophy of the

kidney involved, and may show compensatory hypertrophy of the other kidney. In the x-ray film of the abdomen, attention should be paid to calcification of the great abdominal vessels—a good indication that such changes may exist also in the renal vessels.

Nelson² and others have described a highly accurate diagnostic procedure in the aortogram, but this is too formidable to be of general use. Catheterization of the vena cava and renal vein is now performed in many cases for physiologic and pathological studies, and may be of value. Such a procedure was used in the case reported below.

FIGURE 3 Retrograde Pyelogram Taken Three Weeks after Admission.

This shows still further diminution in size of the right kidney. The configuration remains normal.

and aided immeasurably in the diagnosis by obtaining no blood flow from the kidney involved.

MANAGEMENT

The management of the condition is medical, and the prime requisite is rest. Nothing is to be gained by surgical intervention, and of course the patient is a poor anesthetic risk on account of the possibility of other occlusions. Fluid balance, cardiac failure, function of the remaining kidney and all other general features of the condition deserve the major

consideration, for nothing is to be done for the thrombosis that has already occurred. Total occlusion leaves a functionless kidney, but occlusion of only a major arterial branch may leave enough

FIGURE 4 Post-Mortem Roentgenogram of the Kidneys, Renal Vessels and Aorta.

Note the arterial calcification and the comparative size of the kidneys.

renal function to be of value to the life of a patient whose circulatory apparatus has suffered such severe changes as to allow thrombosis to occur.

CASE REPORT

I. M. G. (A-65313) a 62-year-old woman was admitted to the hospital on April 9, 1946. She complained of pain in the right upper quadrant of the abdomen of 2 days duration. The pain was constant and severe, not colicky in nature and radiated through to the right flank. Nausea and vomiting began shortly after the onset of the pain and persisted until admission. The patient had had no bowel movement for 2 days. The urinary symptoms of hematuria, dysuria and frequency were denied.

The significant past history was confined to the cardiovascular system. The patient was known to have had hypertension for several years. One year previously she had suffered a mild cerebral accident, with aphasia, facial weakness. These symptoms were made a complete recovery. She had worked until the onset of the

Physical examination revealed an elderly woman apparently ill and in acute distress. Significant physical findings were confined to the abdomen and the circulatory system. The abdomen was moderately distended. There was marked tenderness in the right upper quadrant, but no muscle spasm. There was even more marked tenderness in the right costo-vertebral angle, with moderate voluntary muscle spasm. No mass could be felt. Peristalsis was present. Rebound tenderness could not be detected. The heart was enlarged to the left, without shocks, thrills or murmurs. The rate was 76, showing approximately 14 beats per minute dropped, in comparison of the apical and radial rates. The rhythm was irregular, owing to frequent premature ventricular contractions, and the irregularity seemed even more striking at the radial pulse. The peripheral vessels were sclerotic, and the eyegrounds showed marked arteriolar constriction.

The temperature was 100°F, the respirations 18, and the blood pressure 160/80.

A specimen of bladder urine obtained through a catheter was normal except for a faintly positive test for albumin. Examination of the blood disclosed a red-cell count of 4,600,000, with a hemoglobin of 14 gm per 100 cc., and a white-cell count of 18,200, with 88 per cent neutrophils and 12 per cent lymphocytes. The nonprotein nitrogen was 46 mg per 100 cc.

On the basis of these findings the patient was admitted to the Surgical Service for possible gall-bladder disease, appendicitis or partial intestinal obstruction. On the night of admission a urologic examination was performed. Cystoscopy revealed a normal bladder, but no urine was seen to spurt from the right ureteral orifice. Both ureters were catheterized easily, and the urine from the left side was normal. No urine was obtained from the right kidney, although the catheter was proved to be patent and in the kidney pelvis. The right kidney failed to excrete indigo-carmin in 20 minutes, whereas the excretion on the left was prompt and adequate. An excretory urogram showed good excretion on the left, but none on the right. Retrograde pyelography demonstrated that both kidneys were normal anatomically. It was noted in all the roentgenograms that there was calcification of the great abdominal vessels.

A diagnosis of complete occlusion of the right renal artery was made, and the patient was transferred to the Urological Service. The electrocardiographic diagnosis was isolated ventricular premature systoles.

For the next 4 weeks the patient continued to be quite ill. She complained of pain, but it steadily became less. She was semistuporous and lethargic. The blood pressure fluctuated from 160/80 on admission to 250/140, averaging 220/120. The nonprotein nitrogen rose to 68 mg per 100 cc 1 week after admission, and then made a gradual decrease to 32 mg per 100 cc. within 4 weeks.

Five days after admission the patient experienced an episode of gross hematuria, with nausea and vomiting, the skin was cold and clammy, and the blood pressure was at its height. She was nearly comatose, and the prognosis was grave. The hematuria ceased within 24 hours, and no urologic studies were made during that time, so that the source of the bleeding was undetermined. Thereafter, the urine remained clear, but continued to show a positive test for albumin and a low specific gravity.

At weekly intervals during the hospital stay retrograde pyelograms were made, and progressive atrophy of the right kidney was observed. No resumption of renal function on that side was noted. The left kidney remained normal. These serial studies were performed on the same table and with the same technic, so that exact measurement of the atrophy was possible (Fig 1, 2 and 3). The diminution in size was evident at a glance, and measurement revealed a change of 2 cm in length and 7 mm in width within 3 weeks.

Two weeks after admission, catheterization of the right renal vein was performed as a diagnostic procedure. This was done with a No 8 Fr catheter, introduced in a vein in the antecubital fossa and passed up into the subclavian vein, down the superior vena cava and into the inferior vena cava. Under fluoroscopic vision the right renal vein was catheterized, no flow of blood being obtained from this vessel.

Within a month the patient was considerably improved. She was sitting up and eating and was much clearer mentally. Six weeks after admission she was allowed to go home, to be followed weekly in the outpatient clinic.

She did not return to the clinic as directed. Three weeks after discharge she was readmitted through the Emergency Clinic. She was comatose, with a blood pressure of 156/100, a nonprotein nitrogen of 68 mg per 100 cc., and an irregular pulse as previously. She was apparently in extremis and became progressively weaker. She died 48 hours after the second admission.

Autopsy. Post-mortem examination confirmed the diagnosis of complete thrombosis of the right renal artery with bilateral arterioneurosclerosis (Fig 4). There was generalized arteriosclerosis, and the primary cause of death was a myocardial infarction due to thrombosis of the left coronary artery. The splenic artery and abdominal aorta showed the severe calcification as detected by x-ray study.

SUMMARY

The pathogenesis, diagnosis and management of renal-artery thrombosis are discussed.

Renal-artery thrombosis is considered to be one manifestation of generalized atheromatous disease of the arterial system. The condition is more frequent than is generally recognized and can be diagnosed with present methods.

A case of complete occlusion of the right renal artery due to thrombosis in which the ante-mortem diagnosis was confirmed by autopsy is presented.

MILKMAN'S SYNDROME*

Report of a Case

IRVING B. BRICK, M.D.† AND LIEUTENANT COLONEL ROLLIN F. BUNCH, M.C., A.U.S.‡

FROM time to time in routine radiologic bone studies lesions are encountered whose etiology is difficult to determine. Such a case is reported below because of its interest from a radiologic and medical point of view. Milkman^{1, 2} presented a case of multiple spontaneous idiopathic symmetrical fractures in which forty-three fractures were noted and for which no etiology was established. Since Milkman's report 19 additional cases have been reported in the literature, with a review by Edeikin and Schneberg.³ Of these cases, 16 were reported from Europe. All except 1 occurred in women.

The main clinical characteristics of Milkman's syndrome are the predilection for middle-aged women, intermittent hockache, pains in the legs, fatigue, waddling gait, difficulty in changing positions, good nutritional and constitutional condition despite widespread bone changes and, in the later stages, bedfastness. Radiographically, the disease is characterized primarily by generalized osteoporosis and by a multiplicity of symmetrical fractures with inadequate healing. The disease in the early phase is characterized by focal osteoporotic areas, which progress to linear areas of rarefaction known as Looser's zones and generally called "pseudofractures." Above and below the lesions the bone appears normal except for osteoporosis. As the disease progresses, these lesions may give rise to displacement at the site of the fracture, resulting in such deformities as coxa vara, but predominantly there are few cases of displacement and the lesions appear to remain static radiographically, with no evidence of healing.

From a laboratory point of view, nothing pathognomonic has been found. In the case presented below, extensive laboratory studies were conspicuous only by the normality of the findings.

The diseases in which Looser's zones or pseudofractures have been described and thus must be considered in a differential diagnosis are osteomalacia, rickets and late rickets, renal rickets, celiac disease, chronic idiopathic steatorrhea, Gee's disease (intestinal infantilism), nontropical sprue, sprue, osteogenesis imperfecta (early and late), fragilitas osseum, hyperparathyroidism, hyperthyroidism, osteitis deformans (Paget's disease), bone dystrophy secondary to adrenopituitary dysfunction, severe chronic acidosis (hyperglycemia), congenital syphilis, osteomyelitis, osteopetrosis ("marble bones"), march fractures and blood dyscrasias.

Despite extensive study in the cases reported as Milkman's syndrome, no etiologic factor has been revealed, and there is nothing specific from a histologic study of the involved bone.

In the treatment of this condition, as in any disease in which the etiologic agent is unknown, a great many therapeutic agents have been tried without any beneficial results. Primarily, calcium and vitamin A and D therapy have been used most extensively. Other agents that have been used are arsenicals, ultraviolet rays, bone grafts and multivitamins.

Hopf⁴ stated that calcium and vitamin D gave immediate and lasting relief. Debray,⁵ using phosphorus (phospho-calcique) and arsenicals reported a "functional cure." Edeikin³ claimed a remission with vitamin D and ultraviolet-ray therapy. In view of the inability to demonstrate an etiologic agent, the failure of similar therapy in other cases, as well as in the case reported below, and the intermittent clinical character of the condition, it is doubtful that such therapy is of lasting aid in bona fide cases. Thus, another clinical characteristic of this syndrome is its failure to respond to known therapeutic agents.

A 37-year-old man had felt perfectly well until March 1943. He had had 21 years of service in the Army and until the onset of the present illness had served satisfactorily. At that time while returning from a 27 mile road march he slipped and fell injuring the right hip. He was able to continue the march although the hip hurt. The pain continued with some radiation down the right thigh to the knee. For the next 2 months he had intermittent severe pain in the hip as well as in the lower part of the back and was seen on sick call at various intervals. In June the first x-ray films of the hip were taken and revealed some thinning of the osseous articular cortex and a minor degree of generalized osteoporosis of the head of the right femur and the adjacent acetabulum. Some shortening of the neck of the right femur, with anterior angulation of the head on the neck was also noted. A diagnosis of traumatic arthritis of the right hip was made and the orthopedic consultant noted a 2-cm. shortening of the right lower extremity. The patient was sure that the limp had begun after the injury in March and denied previous injury or a possible old fracture and the Army records confirmed these facts. The patient was returned to duty and the pain in the right hip, low back and legs continued.

In August the patient went through mustard gas in a gas chamber and burns of both legs below the knee and on the right forearm developed. The resultant rash was first red and healed slowly being replaced by a brownish pigmentation that remained particularly on the right leg. In the same month he was again hospitalized. X-ray films were obtained and he was returned to duty with a diagnosis of arthritis of the right hip. The x-ray films of the lumbar spine, pelvis, chest and hip again revealed only the lesion in the right hip. The report stated that the femoral head had the appearance of an old slipped epiphysis that had fused in malposition without undue destruction. It was noted at that time that the patient had a distinct waddling gait. The observation was made that, despite the fact that the general clinical impression and x-ray examination suggested long

standing illness, the symptoms were of relatively recent origin. In November the patient was transferred to an armored division and because of the continued pain and limp was unable to perform duty satisfactorily. By February there seemed to be some alleviation of the pain, but at that time a rash developed on both legs below the knees and on the right forearm. This was over the skin area that had been subjected to the mustard burn some months previously. The patient was transferred from several units

Physical examination revealed a patient who was 5 feet, 7½ inches tall. The skin was clear except for brown areas of pigmentation over both legs extending from 10 cm. below the knees to just above the ankles. There was a large brown pigmented area on the lateral side of the left foot. The eyes, ears, nose and throat were normal. There were no palpable lymph nodes. The heart and lungs were normal. The abdomen revealed no tenderness, palpable viscera or masses. The genitourinary system was normal. Rectal examination was negative. The patient walked with a marked limp and a waddling gait. He had difficulty in movement requiring flexion of the low back or right hip. The right leg was approximately 4 cm. shorter than the left. Motion was free in all normal excursions in the left hip. There was slight tenderness over the right sacroiliac region and in the right hip joint. There was no noticeable scoliosis of the spine. There was moderate generalized weakness but no gross

FIGURE 1 *Pseudofractures of the Spinous Processes of the Fifth, Sixth and Seventh Cervical Segments, with Generalized Osteoporosis and Biconcave Lower Cervical Bodies*

because of inability to perform duty satisfactorily. The pain and stiffness prevented him from getting out of a chair rapidly or from walking fast, and he stumbled and fell rather frequently. Because of the continuing difficulty, he was again admitted to an Army hospital on March 16, 1945.

In the interval there had been an increase in the difficulty in walking, in the limp with waddling gait, in the pain in the low back and the right hip and occasionally in the right leg. These symptoms had remained practically unchanged to date. The patient's general health had otherwise been good, and he had gained about 10 pounds in weight since the onset of the illness.

The patient had served in Panama from 1924 to 1930, in Hawaii from 1930 to 1933 and from 1938 to 1940. The patient drank occasionally and smoked about 1½ packages of cigarettes daily. He used no habit-forming drugs.

The patient's mother was living and well at 68 years of age, and his father, 70 years of age, was in good health. The patient had two siblings, both living and well. There was no family history of diabetes, tuberculosis, syphilis or cancer. No member of the family, to his knowledge, had had arthritis, bone disease or nervous or mental disorders.

The patient had had the usual childhood diseases but no scarlet fever, diphtheria or rheumatic fever. He had had malaria in 1926 while in Panama, but there had been no recurrence. In 1942, after an inoculation for yellow fever, he had a mild case of jaundice with no sequelae. There had been no injuries of significance.

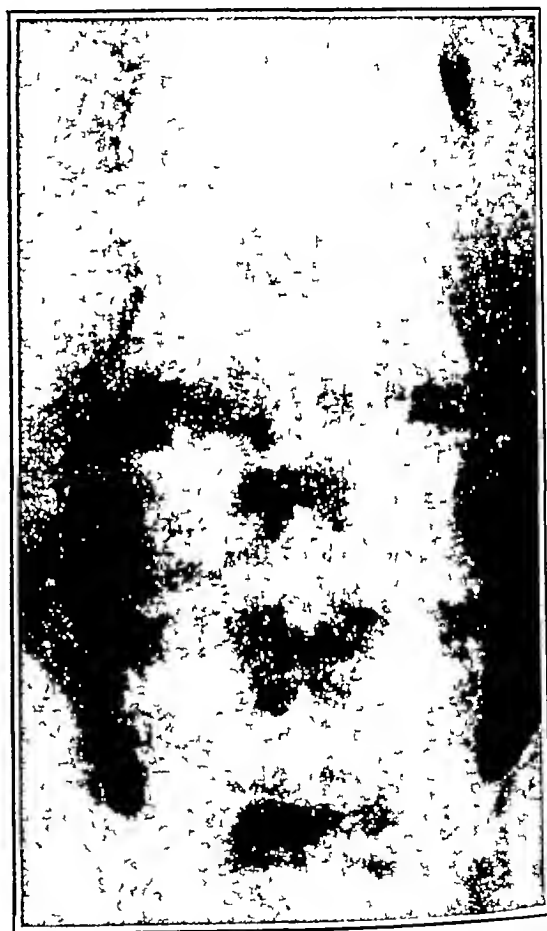

FIGURE 2 *Bilateral Interarticular Isthmus Hiatus of the Third, Fourth and Fifth Lumbar Segments*

atrophy of the muscular system. Neurologic examination was negative, and the reflexes were physiologic.

The blood pressure was 120/80.

X-ray studies in March, 1945, disclosed a moderate degree of generalized osteoporosis. An irregular longitudinal line of rarefaction extending across the superior margin of the left acetabulum was noted. There was no evidence of cartilage destruction in the joints. Little or no bone production was noted in any of the localized areas of bone destruction. There was no bowing of the femurs. The bone changes were noted to be predominantly within the cortex. Later x-ray films revealed narrowing of the bodies of the fifth and sixth dorsal vertebrae and pseudofractures of the spinous processes of the fifth, sixth and seventh cervical vertebrae (Fig. 1). Further x-ray changes included generalized osteoporosis and pseudofractures of the interarticular isthmus hiatus bilat

erally in the third, fourth and fifth lumbar segments (Fig 2) of the second to the fourth and the sixth seventh ninth tenth and eleventh left ribs and the second, seventh, eighth and tenth right ribs, of the manubrium of the acromioclavicular processes and the middle thirds of both scapular bodies below the spines (Fig 3), of both radial necks (Fig 4), of

examination showed a red-cell count of 5,500,000, with 16.09 gm of hemoglobin, and a white-cell count of 5600, with 52 per cent neutrophils, 47 per cent lymphocytes and 1 per cent monocytes. The clotting time was 3 minutes, and the bleeding time 2 minutes. The hematocrit was 47 vol. per cent, with a sedimentation rate of 7 mm in 1 hour.

the distal phalanx of the left middle finger (Fig 5), of the superior margin of the left acetabulum (Fig 6), of the neck of the right femur with a coxa vara deformity (Fig 7) and of both patellas (linear). An intravenous pyelogram

Blood Kahn and Wassermann tests were repeatedly negative. Examination of the spinal fluid was within normal limits. Repeated urinalyses showed only one significant finding — a 4+ Benedict's test for glucose on several examinations.

FIGURE 4 Bilaterally Symmetrical Pseudofractures of Both Radial Necks

did not reveal any renal abnormality. Examination of the gastrointestinal tract, including the small intestine, was within normal limits.

During the past year the patient has undergone intensive laboratory study without any diagnostic findings. Repeated hematologic studies were within normal limits. The last

Many examinations, however, were negative for sugar. Fasting blood sugars ranged at various times from 75 to 85 mg. per 100 cc. and glucose tolerance tests were negative. The last such test performed showed a fasting blood sugar of 82 mg. per 100 cc. with a rise to 152 mg. in 1½ hours and a decline to 97 mg. in 1½ hours and to 88 mg. in 2 hours.

Benedict's test, however, was ++++ for glucose after the control. This was repeated, and practically the same results obtained, indicating a low renal glucose threshold. The serum alkaline phosphatase ranged from 5 to 15 Bodansky

hydrochloric acid values of 39, 14, 40, 53 and 30 clinical units. The total serum protein on the last examination, which was typical of the others, revealed 6.34 gm per 100 cc., with 4.9 gm of albumin and 1.43 gm of globulin. Repeated

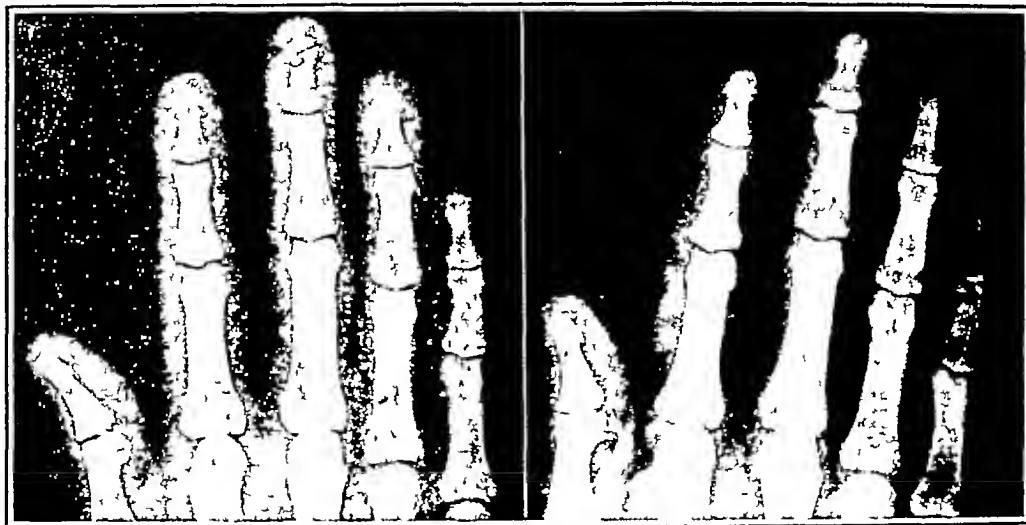

FIGURE 5 Roentgenograms of the Fingers of the Left Hand

units, the last such examination on July 18, 1946, revealed 14.7 Bodansky units—a slight elevation. The serum acid phosphatase was within normal limits. Various determina-

examinations of the feces showed no starch granules, no increase in the fat content and negative examinations for occult blood and parasites or ova. Basal metabolic rates

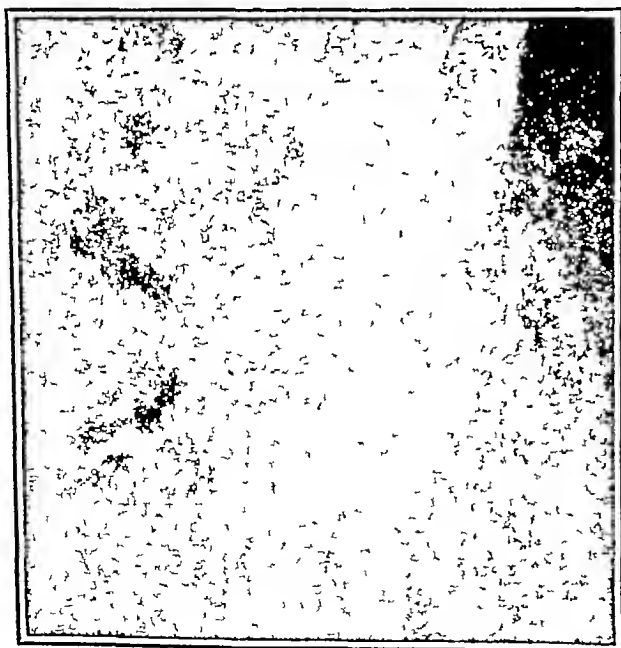

FIGURE 6 Pseudofracture of the Left Ilium Extending across the Superior Portion of the Acetabulum

tions of the serum cholesterol and cholesterol esters were normal. Repeated examinations of the urine for Bence-Jones protein were negative. The icteric index was normal, as were the cephalin-flocculation and bromsulfalein tests. A fractional gastric analysis with histamine revealed free

FIGURE 7 Fracture of the Neck of the Right Femur, with a Coxa-Vara Deformity

were obtained at varying intervals and ranged from -11 to +13 per cent. The Congo-red test was negative.

Extensive and repeated calcium-balance studies were obtained over an 18-month period without revealing significant results. In various laboratories and at various times during this interval the blood phosphorus ranged from 1.6 to 3.8 mg per 100 cc., and the calcium values ranged from 8.8 to

11.8 mg per 100 cc. Between the extremes numerous normal values were obtained, and repetition of the chemical studies always resulted in further normal values on the follow up examination.

Special studies were done after the patient had been placed on a diet containing approximately 0.1 gm. of calcium daily for 2 weeks. The serum alkaline phosphatase was 117 Bodansky units, the serum acid phosphatase 0.1 Bodansky unit, the serum phosphorus 2.15 mg., and the serum calcium 9.9 mg per 100 cc., the 24-hour fecal phosphorus was 64.8 mg., the 24-hour fecal calcium 304 mg., the 24-hour urine phosphorus 761.6 mg., the 24-hour urine calcium 112 mg., and the 24-hour urine 17 ketosteroids 10.8 mg.

Studies of the blood chloride, uric acid and blood urea nitrogen were within normal limits. The blood phosphatase was slightly elevated on most examinations, and the phosphorus content of the serum was at the lower limits of normal.

Repeated electrocardiograms were within normal limits. A biopsy from the right tibia on May 2, 1945 revealed no areas of fibrosis, and the segment of cortex appeared thin. The Haversian canals were extremely large, and a diagnosis of rarefied bone was made. Biopsy of the skin over the pigmented area on the left leg was reported to show hyperpigmentation of the skin with atrophy.

For 1½ years the patient's condition changed little. There was some progression of the x-ray changes but the general physical condition remained unimpaired. From time to time the patient had greater degrees of pain in the lower back, right hip and legs. He was seen by various orthopedic consultants, who believed that no orthopedic treatment was indicated for the shortening of the right leg. Treatment with large amounts of various preparations of vitamins D and A, of calcium given both orally and parenterally of multiple vitamins and of high caloric and high vitamin diets did not result in any change in the bone condition. The patient gained weight during hospitalization and had no complaints other than the difficulty in walking. He was able to walk short distances with a cane but had difficulty in getting out of bed unaided and in arising from the sitting position. Physiotherapy afforded some symptomatic relief of pain.

This case is considered to fall within the criteria for the diagnosis of Milkman's syndrome. The various conditions in which pseudofractures occur were satisfactorily eliminated, both clinically and by laboratory means. This case, in which the patient presented thirty-nine fractures, is typical of the chronicity of the condition. Autopsy has been reported in only 1 case, after eight years of observation, and nothing of pathognomonic value was found on histologic study.²

The case reported above is somewhat unique in that it occurred in a male, only 1 similar case having been reported.³

Camp and McCullough,⁷ in a learned discussion of pseudofractures, point out the varied and diverse diseases affecting the skeletal system in which such lesions occur, and deny the existence of this distinct clinical entity. In the diseases listed by them, however, careful clinical study would ordinarily lead to a definitive diagnosis, since the pseudofractures are but a minor finding in these conditions. In the group of cases under discussion as Milkman's syndrome, the obvious features of the disease in differential diagnosis listed by Camp and McCullough are absent and what remains is a distinct syndrome of unknown etiology.

SUMMARY

A case of Milkman's syndrome occurring in a male is reported.

A brief review of the literature and differential diagnosis is presented.

Subsequent to the preparation of this paper Albright and his associates,⁴ in a presentation wealthy in metabolic data, conclude that Milkman's syndrome is a form of osteomalacia, underlying which there may be various etiologies. Emphasis is placed on osteomalacia resulting from a specific form of renal acidosis tubular insufficiency without glomerular insufficiency. They too disagree with Camp and McCullough and believe that the ribbon-like zones of decalcification called "pseudofractures" by some authors are found only in Milkman's syndrome and are consistent with underlying osteomalacia. The various etiologies listed in this article explain why therapy must necessarily differ to be efficacious in all cases of Milkman's syndrome.

MEDICAL PROGRESS

CHEMICAL FACTORS IN ASTHMA*

JOHN G. WISWELL, M.D.,† AND FRANCIS M. RACKEMANN, M.D.‡

BOSTON

KNOWLEDGE of what takes place within the patient during a paroxysm of asthma or during an attack of urticaria is not at all clear. Such simple matters as the balances of water, salt or acids and bases have been observed in asthma and in other so-called "allergic diseases," but few of the studies are sufficiently controlled to establish any definite conclusions. The fact is that the available data are often conflicting and therefore confusing. For example, some practitioners treat their patients by withholding salt and water, and others by administering salt and water by mouth and by vein, each group claiming good clinical results. Acids are given sometimes in large amounts, and good effects are reported from the treatment, alkalies are given by other authors, apparently with similar success. The feeding of potassium is advised in some cases, and the injection of calcium in others. Vitamins are administered in the hope that the extra quantities will be beneficial.

It is quite evident that present impressions derive almost entirely from clinical observations. Good experiments, carefully devised and carefully executed with proper controls, are mostly lacking. If patients are to be treated with uniform success, the rationale of treatment must be understood—the physiologic reasons as well as the clinical indications for the different procedures and the results that can be expected must be known. Before these matters can be investigated, a review of the literature is necessary, and since the literature is voluminous and is not without clinical interest, the published papers that have a bearing on this are discussed.

THE ACID-BASE BALANCE

In 1928 Crip and McElroy¹ observed that some cases of urticaria improved following the administration of dilute hydrochloric acid. By the Rehfuess technic the gastric contents of 65 healthy medical students and of 50 patients suffering from asthma or other allergic conditions were examined, a complete lack of hydrochloric acid in 36 per cent and a hypoacidity in another 32 per cent being reported. The authors concluded that a low gastric acidity, although not constant in allergy, was much more frequent than in normal persons. In 1930 Beckman² considered "potential alkalosis" a causative factor

in allergy. By this he meant that the allergic person tended to store up too much alkali or to neutralize too effectively the acid substances produced during normal metabolism, and he cited the low incidence of allergy in patients with diabetes, starvation, pregnancy and acute infectious diseases, in all of which he claimed that there was a tendency to acidosis. He stated that the allergy improved when the patient was rendered more acidotic, as by treatment with calcium, whisky and acetylsalicylic acid or mineral-acid therapy. Beckman treated 237 cases of hay fever with nitrohydrochloric acid (4 cc. of a 15 per cent aqueous solution four times a day) and obtained improvement in 65 per cent. Unfortunately, he did not present any figures to show the degree of acidosis, and in the cases that improved under acid treatment he did not mention environment, weather or pollen counts, which might also have explained the good result.

In 1936 Loveless³ studied the gastric contents of 138 children and adults with allergic diseases an hour after the ingestion of an Ewald meal. In contrast to Beckman, she could not find any significant deviation from the normal level of gastric acidity, nor did intensive hydrochloric acid therapy—4 cc. of dilute hydrochloric acid (USP) three times a day—influence the acid-base balance as shown by the bicarbonate-tolerance test and by studies of the plasma carbon dioxide content. The alkali reserve was not lowered to any appreciable extent. Clinical results on the patients receiving intensive acid therapy did not show any beneficial effects.

Evidently, then, potential alkalosis is not a constant factor in patients with allergy. On the contrary, the poor pulmonary ventilation in asthma causes a retention of excess carbon dioxide in the blood and a compensatory rise in the plasma bicarbonate level. When a nonvolatile acid like hydrochloric acid is administered it will combine with the bicarbonate, releasing carbon dioxide, and the chloride will be excreted by the kidneys. If the excess carbon dioxide can then be eliminated by the lungs, all will be well, if not, dyspnea may become increased, for it is the accumulation of carbon dioxide, as well as the anoxemia, that causes the distress in these patients. If alkali is administered it will compensate for the excessive carbon dioxide for a time, and the normal ratio between carbonic acid and bicarbonate will be established at a higher level. Eventually, however, a limit is

*From the Allergy Clinic, Massachusetts General Hospital.

†Research fellow in medicine, Massachusetts General Hospital.

‡Physician and chief Allergy Clinic, Massachusetts General Hospital; lecturer in medicine, Harvard Medical School.

reached the lungs cannot blow off more carbon dioxide, the kidneys cannot take care of the base, and meanwhile the excessive carbon dioxide in the blood diminishes the content of oxygen. Dyspnea increases dangerously, the treatment may thus do harm.

SODIUM, POTASSIUM AND WATER BALANCE

It is well known that sodium potassium and chloride are vital to the regulation of the normal intracellular fluid electrolyte balance. Most of the sodium and the chloride ions are contained in the plasma of the blood and in the interstitial fluids, whereas most of the potassium resides in the tissue cells. Potassium leaves the cells when their membrane permeability is altered, or when increase of acid in the blood draws base from the inside of cells. Thus, muscular activity causes a movement of potassium from cells into the body fluids. Potassium is also lost from cells when there is a loss of total salt and water, as in hemorrhage or burns. Trauma, intestinal obstruction, severe infections and Addison's disease, which cause a loss of body sodium, pull out cellular potassium. In hypertension or after an injection of adrenalin, there may be an increase of serum potassium. It is also known that an infusion of sodium chloride or stimulation of the central vagus nerve will result in an increase of serum potassium. Sodium and potassium ions tend to increase neuromuscular excitability, and potassium is said to be concerned with the release of acetylcholine at nerve endings.

The normal level of potassium in the blood ranges between 3 and 5 milliequiv per liter. In 1927 Klyn⁴ first called attention to abnormally high levels of potassium in the blood serum of asthmatic patients, he found an average value of 6.5 milliequiv per liter in 40 patients. Unfortunately, Unshelm,⁵ in 1929, and Lierle and Sage,⁶ in 1932, could not repeat his results; they reported normal levels of 5 milliequiv per liter. In 1937 Rusk and Kenamore⁷ claimed that potassium therapy was indicated in urticaria, stating that potassium metabolism was markedly altered in skin inflammation and irritability, and that an increase in skin potassium caused an appreciable decrease in localized irritability. They pointed out that potassium is similar to adrenalin in its pharmacologic action. In 6 patients with chronic urticaria a high-protein, low-sodium, acid-ash diet was used, with 4 to 6 gm of potassium chloride added daily, and good results were obtained. No laboratory figures to support the theory were presented, however, and the number of cases was too small for any definite conclusions to be formed. In the same year Wenner and Buhrmester⁸ reported the liberation of an acetylcholine-like substance in rabbits during anaphylactic shock, which they thought was caused by the marked increase in serum potassium that they found. They admitted that the specific action of potassium on

the vegetative nervous system was extremely uncertain.

In 1938 Cohen,⁹ following the suggestions of Rusk and Kenamore,⁷ treated 8 cases of chronic urticaria with a high-protein, low-sodium, acid-ash diet with added potassium chloride, but he did not find improvement in any case. Bloom¹⁰ thought that allergy might be basically an endocrine dysfunction with secondary disturbances of electrolyte metabolism. He treated 29 cases of hay fever with 0.3 gm of potassium chloride three times daily, and obtained good results, a few cases of eczema, nasal polyposis, acute urticaria, chronic allergic sinusitis and migraine also improved under the same therapy. Patients with chronic urticaria were not benefited. It is difficult to see how such a small dose of potassium chloride could alter the body electrolyte balance, the author did not present any laboratory studies, nor did he mention other variable factors that influence hay fever, such as atmospheric conditions and environment. Rusk, Weichselbaum and Somogyi¹¹ reported serum potassium levels above normal in 20 patients with urticaria and in 10 patients with bronchial asthma. They postulated that potassium was released from the cells and that, if an excess of potassium was fed, the cellular loss would be replaced and the symptoms would be improved, some patients so treated obtained relief.

This new idea of treatment with potassium drew a variety of papers from American clinics. Using approximately 1 gm of potassium chloride daily in various numbers of patients with allergic disorders, Harley,¹² Harsh and Donovan,¹³ Rubin and his associates,¹⁴ Engelsher¹⁵ and Furstenberg and Gay¹⁶ could not produce any appreciable benefit. Abt¹⁷ obtained good results in patients suffering from hay fever and asthma, but his therapy with potassium chloride was given in October after the hay-fever season was over. Parker¹⁸ reported that persons with asthma, hay fever or vasomotor rhinitis who received potassium chloride or potassium gluconate were generally benefited.

Reports on the influence of sodium and water on patients with asthma and allied disorders are also numerous. Pitressin, the antidiuretic principle of the pituitary gland, causes not only a retention of body water but also a coincident absolute increase in the output of sodium and of chloride in the normal subject. Cook and Stoesser¹⁹ believed that this action offered a unique opportunity to dissociate the effects of water and salt in the asthmatic patient; they gave 6 asthmatic children a low-sodium diet and also Pitressin in doses of 0.3 to 0.5 cc. every three hours for eight doses, or until there was a gain in weight due to the water retention, and when this occurred the asthma improved. Acute symptoms developed in 1 case when a dose of 0.6 gm of sodium chloride was given. The authors suggested that the sodium ion exercised an adverse influence,

on the asthmatic patient, independent of its usual relation to hydration

In 1939 Sheldon, Howes and Stuart²¹ speculated on the relation of general body water and sodium to the local tissue edema occurring in allergic disease. They studied water and sodium metabolism in 5 asthmatic patients, measuring carefully the diets, intake and output. They found that, during prolonged asthmatic attacks, there was a definite loss of body water and sodium. In the following year Stoesser and Cook²² reported further investigations. In 12 asthmatic children they varied the electrolyte metabolism by different procedures and found no consistent changes in the levels of potassium, chloride or sodium in the blood serum. In some cases they observed remissions when the patients were given a diet with low-salt content and at the same time were treated with artificial fever, but asthma recurred when 1 or 2 gm of sodium chloride was added to the diet. In other cases, when 6 to 10 gm of potassium chloride daily was added to the low-sodium diet, mild attacks of asthma ceased, but the severer ones continued, when the potassium chloride was discontinued, the latter ceased. The authors concluded that the amounts of sodium, potassium and chloride in the diet were of importance in the control of bronchial asthma occurring in children, but they did not explain the reason for the beneficial effect of either the restriction of sodium chloride or the administration of potassium chloride.

Further studies on changes in serum sodium concentration in allergy were made in 1940 by Donovan and Harsh,²³ who determined the serum sodium concentrations of 50 patients suffering from asthma, urticaria or allergic rhinitis and of 133 persons who gave no personal or family history of allergy. The concentrations of both patients and controls fell within normal limits, and the authors concluded that there was no evidence of a direct connection between the allergic symptoms and the concentration of sodium in the serums of the allergic patients. In 1940 Kern,²⁴ discussing water balance in allergy, presented the theory that changes in the water balance of the body influence the occurrence of allergic phenomena. His statement was as follows:

Water and salt retention will favor the development of allergic reactions. Dehydration and salt loss will antagonize allergic reactions. Increased intake of sodium, by tending to increase interstitial fluid and edema, will also favor the development of allergic reactions. Increased intake of potassium or decreased intake of sodium, will antagonize allergic reactions. Such shifts of water balance occur clinically in a variety of conditions, or they may be induced by a number of therapeutic measures. But the effect of hydration and dehydration on allergic reactions is purely nonspecific, and consequently the causes initiating changes in water balance must not have attributed to them any specific etiologic significance in the causation of the allergy itself.

In 1941 Kinsell and Zwemer²⁵ attacked the problem by another method. They studied the

level of potassium in the blood of guinea pigs in anaphylactic shock. They sensitized 34 animals with 0.25 cc of horse serum, and gave the second (shock) dose intraperitoneally one to four weeks later. In animals in which anaphylactic shock of rapid onset and marked intensity was produced, they observed a definite rise in plasma potassium, which was greater than could be accounted for by the hemoconcentration, as measured by the red-cell volume and the plasma protein. This was in contrast to the control group, which showed hemodilution, lowered plasma protein and, in some cases, lowered potassium. The authors did not understand the mechanism of the rise in potassium, but they assumed that there was a loss of potassium by cells due to either a change in cell-membrane permeability or a disruption in the hypothetical intracellular potassium colloid complex, or both. Since injections of potassium salts produce many symptoms of shock, these findings suggested that the use of large amounts of potassium in allergic conditions was contraindicated rather than indicated.

In the same year Sullivan²⁶ was doubtful whether potassium and calcium influenced the local water balance by physicochemical changes or by pharmacologic effects on the nervous system. He treated 29 patients — mostly asthmatics — 13 with 25 per cent potassium chloride solution and 16 with calcium gluconate. Neither group experienced any marked degree of relief of symptoms, and in neither group did the levels of calcium, potassium and chloride in the blood show any deviation from normal values.

In 1942 Stoesser,²⁷ who had studied the effects of potassium therapy in children with asthma, turned his attention to infants with eczema. It had been shown by Holt and others that infants had a higher content of water and of sodium chloride and a lower potassium-sodium ratio than older children, these features disappeared with growth, but in the child with eczema the disappearance was slow. Stoesser gave 4.0 gm of potassium chloride daily to some of his eczematous infants. During the acute eczema the serum potassium level was above normal both in the treated infants and in the untreated eczematous cases, but when the oozing subsided the values for potassium became normal in both groups. Meanwhile, the serum sodium and chloride were normal in all cases and during all stages of the eczema. The author concluded that there was a marked disarrangement of the normal electrolyte balance, that in eczema the threshold for excretion of potassium was raised so that the tissue cells had a high content of potassium and that therapy with potassium chloride was therefore not indicated.

In 1942 Harsh and Donovan^{28, 29} studied 12 asthmatic children. At first they fed a diet normal in sodium but high in potassium, with the daily addition of 7.5 gm of potassium chloride, and found little change in the asthma. When, however, they fed a diet normal in potassium but high in

sodium, with 60 gm of sodium chloride added daily, the children were worse, and, furthermore, the blood potassium was even higher than it had been on the high-potassium diet. The blood sodium, on the other hand, was lower than that in the non-allergic children on the same diet, and more sodium was excreted in the urine.

In 1939 Rubin and Rapoport²⁰ had claimed that injections of potassium chloride with restriction of sodium protected guinea pigs from a shock dose of antigen. To confirm this evidence, Carlson and Whitehead²¹ sensitized guinea pigs with sheep serum and determined the minimum lethal dose of the antigen. When they administered the shock dose of the antigen they gave at the same time sodium thiosulfate, potassium chloride or potassium thiosulfate. They found that sodium thiosulfate showed no inhibitory effect on the anaphylactic reaction, but that potassium, either chloride or thiosulfate, afforded protection against the minimum lethal dose of antigen. From previous observations in their clinic Stoesser and Booth²² had assumed that the depletion of body sodium, however produced, relieved the symptoms in patients with asthma. They then subjected children with chronic asthma to various other forms of therapy. To one group they administered 2 to 12 gm of potassium chloride daily and kept the sodium and chloride intake constant. This treatment produced a diuresis with loss of sodium, and there was an apparent improvement in the asthma. To another group they gave 1 to 10 gm of sodium chloride, 8 to 20 mg of desoxycorticosterone acetate and 8 cc. of adrenocortical extract each day. Like Harsh and Donovan, they noted that with the retention of sodium and the excretion of potassium the symptoms of asthma increased in severity.

From the above it is obvious that the literature contains evidence concerning the roles of potassium, sodium and water in allergy that is confusing if not conflicting. Some workers (Rusk,⁷ Bloom¹⁰ and Parker¹²) claim improvement of patients with allergic conditions by potassium therapy. Others (Cohen,⁹ Harley,¹² Harsh and Donovan,¹² Rubin,¹⁴ Engelscher,¹⁵ Furstenberg¹⁶ and Sullivan¹⁷) find no appreciable benefit from such therapy. Stoesser and Cook^{18, 20, 22} claim that asthma is aggravated by retention of water and sodium. In our clinic patients with severe asthma who become dehydrated and who improve after administration of water and sodium chloride (isotonic solution) are seen. So far, it can be concluded only that any marked shift in water balance one way or the other may aggravate or improve asthma. There is no evidence that changes in electrolyte and water balance are specific or that they are a fundamental factor in the symptom complex.

CALCIUM, PHOSPHORUS AND MAGNESIUM

Another drug formerly used with some enthusiasm in the treatment of asthma is calcium, which has

an effect on nerve and muscle irritability. Whereas an excess of total calcium has little effect on the function of the nervous system, a reduction in ionized calcium excites the peripheral and central nervous systems. Calcium deficiency affects primarily the peripheral neuromuscular mechanism. Bronk and his associates²³ have shown that autonomic ganglion cells are stimulated by a decrease in calcium concentration so that the cells are more readily excited by acetylcholine, whereas an increase of calcium blocks transmission. In addition, it is stated that calcium decreases the permeability of capillaries, although there is little experimental evidence in support of this contention. Because of their effect on ganglions and capillaries, calcium salts have been widely used for the control of inflammation and edema in asthma, urticaria and angioneurotic edema. Unfortunately, the use of calcium in practice has not supported the theory.

Tainter and Van Deventer²⁴ tested the effect of calcium lactate on the experimental edemas produced in rabbits and cats by such drugs as paraphenyldiamine and mustard but could not demonstrate any protective action.

In 1928 Cnep and McElroy¹ determined the blood calcium level in patients with asthma, urticaria or angioneurotic edema. In a group of 40 nonallergic persons the normal value was observed to be 10.43 mg per 100 cc. In 80 patients with asthma the total blood calcium was 10.08 mg, in 43 cases of hay fever it was 10.55 mg, in 21 cases of urticaria 9.66 mg, and in 2 cases of angioneurotic edema 10.40 mg per 100 cc. Their conclusions were that a deficiency of calcium does not exist in atopic conditions, that calcium therapy, as lactate given in doses of 5 gm three times daily for twenty days with parathyroid extract, has little if any influence on the blood calcium of allergic patients, and that the rationale of calcium therapy, because some allergic patients improve after intravenous administration of calcium, is based on the idea that calcium depresses all tissues, especially the nervous system, and tends to lessen the permeability of tissue cells and thus to reduce transudation, which is a frequent manifestation in the shock organs of allergic patients. Sterling²⁵ found normal blood calcium levels in 62 of 85 allergic patients, and blood phosphorus levels below the normal, which he called 3.0 to 4.5 mg per 100 cc, the method of determination not being reported. He claimed a marked symptomatic improvement in a high percentage of patients who were "put on phosphorus," and his theory was that the offending allergens were converted into harmless substances by enzymes activated by the phosphate. This theory has not been substantiated, and successful treatment with phosphorus has not been reported by others.

In 1929 Greenberg and Gunther²⁶ thought that a study of the diffusible calcium might give different results from those of total blood calcium in allergic persons. They analyzed the bloods of 14 patients

with various allergic disorders, and found that the diffusible calcium varied between 40 and 56 mg per 100 cc, their figures for nonallergic adults varied from 45 to 60 mg per 100 cc. In their cases the total and diffusible calcium of the blood serum varied together and within the normal range. Cantarow,³⁷ however, found a definite and quite constant increase in the ratio of diffusible to non-diffusible calcium in the blood in 25 cases of bronchial asthma, and he considered the disturbance of calcium balance to be related to the increased capillary and cellular permeability that was believed to exist in bronchial asthma and allied disorders.

Ramirez³⁸ picked 50 patients with asthma, 50 with hay fever and 50 with urticaria in whom the levels of blood calcium were less than 10 mg per 100 cc. If calcium could help allergic patients, it should have done so in this group. After calcium therapy the levels of calcium in the blood were slightly increased, but there was little clinical improvement. Kern and Teller³⁹ showed that blood calcium was normal (9 to 11 mg per 100 cc) in nearly all of 88 cases of asthma—both allergic and “infectious.” Lierle and Sage⁶ also found normal levels of calcium and phosphorus with normal serum protein concentrations in the bloods of 20 asthmatic patients. In 1931 Crandall and Feinberg⁴⁰ observed the average level of serum phosphorus to be 3.57 mg per 100 cc in 75 allergic patients. In contrast to Sterling³⁵ they concluded that the level of inorganic phosphorus in the serum of the fasting allergic person was within normal limits.

Magnesium is essential for the functional integrity of the neuromuscular system—it blocks muscular contraction, produces a true depression of the central nervous system and has a local anesthetic action on peripheral nerves. It also causes respiratory failure when used as a depressant, the fact that this can be relieved by administration of calcium indicates an antagonistic action of the two drugs.

In 1938 Braden and Braden⁴¹ studied the levels of magnesium in the blood serum of 30 patients with allergic symptoms and found the values to be well within the range of normal variation. Haury,⁴² observing that anaphylactic shock in sensitized guinea pigs could be prevented by raising of the serum magnesium before the test injection, analyzed the blood of 66 patients suffering with bronchial asthma. Half the patients with acute asthma showed low values for serum magnesium. He concluded that a deficiency of the magnesium ion was a contributing factor in asthma by upsetting the neuromuscular mechanism but that hypomagnesemia was by no means an essential etiologic factor. Two of his patients, at the height of an asthmatic paroxysm, were given 20 cc of 10 per cent magnesium sulfate intravenously and 4 cc of a 50 per cent solution of the same drug intra-

muscularly, and were relieved for approximate twenty-four hours.

Thus, according to the majority of workers, it is evident that there is no important disturbance of calcium, of phosphorus or of magnesium metabolism in allergic patients. Treatment with these compounds is certainly not specific. As outlined above, if it does good at all, the mechanism can depend only on the pharmacologic effect of these substances on the neuromuscular mechanism.

(To be concluded)

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., Editor

BENJAMIN CASTLEMAN, M.D., Associate Editor

EDITH E. PARRIS, Assistant Editor

CASE 33361

PRESENTATION OF CASE

A fifty-nine-year-old schoolteacher was admitted to the hospital because of jaundice and malaise.

About a month before admission the patient had begun to notice slight nausea. Two weeks later severe malaise and increasing weakness appeared, and ten days before admission, jaundice, light stools and dark urine were noted. The jaundice increased, becoming severe, until two days before entry, when it seemed to decrease, but without change in the urine or stools. The patient had had chilly sensations but no real shaking chills, and she had felt hot. There was no pain or abdominal tenderness, the appetite had decreased somewhat, and she had lost 7 pounds in the last ten days. There was no history of exposure to other jaundiced people or chemicals or of alcoholism. There was some intolerance to greasy foods.

The past history revealed that at the age of thirty-five, at about the fourth month of pregnancy, an appendectomy had been performed in this hospital. The patient was readmitted fourteen years later because of epigastric pain of a year's duration, associated with frequent eructations and regurgitation of food. Five weeks prior to that admission, she had vomited about half a cupful of blood, and she had subsequently vomited small amounts of blood on four or five occasions. X-ray films at that time revealed a hiatus hernia involving about a fourth of the stomach. The left phrenic nerve had been crushed, with subsequent improvement of the symptoms. The diagnosis at that time was asymptomatic cholecystitis. Another x-ray film on discharge revealed no hiatus hernia. Subsequently she was

well for seven or eight months, after which the symptoms recurred. Despite difficulty in swallowing the patient maintained her weight at about 170 pounds. Additional information revealed joint pains, thought to be rheumatic fever, forty years previously and a vaginal repair twelve years previously. Also, for the past fourteen years, she had had occasional attacks of dyspnea, especially on exertion, associated with sharp precordial pain and relieved by rest.

Physical examination revealed a well developed, obese, markedly jaundiced woman with a perforated nasal septum and large submaxillary, axillary and supraclavicular lymph nodes. The heart and lungs were normal. The abdomen showed an area of local tenderness in the right upper quadrant. The cervix was absent, and there was a firm nodule in the left vaginal vault. The left knee was enlarged and stiff, and the left ankle was ankylosed. The right second metacarpal phalangeal joint was enlarged. There was slight edema of both shins, and varicose veins bilaterally, with discoloration around the left medial malleolus.

The temperature was 100.6°F, the pulse 80, and the respirations 20. The blood pressure was 150 systolic, 80 diastolic.

Examination of the blood revealed 11 gm of hemoglobin and a white-cell count of 8000, with a normal differential count. The urine had a specific gravity of 1.010 and gave a +++ test for albumin and a +++ test for bile. The sediment contained innumerable white cells. A stool was clay colored and guaiac positive. X-ray examination revealed clear lung fields, a slightly enlarged heart in the left ventricular region and a tortuous aorta. The abdomen contained several areas of calcific density, overlying the region of the gall bladder, that resembled laminated gallstones. The liver and spleen were not enlarged. A barium enema showed numerous diverticula from the distal transverse colon to the rectosigmoid. A gastrointestinal series disclosed a large hiatus hernia, at times ballooning out to more than 5 cm in diameter and causing considerable obstruction of the passage of barium through the cardia of the stomach, which lay above the diaphragm, with the result that the esophagus ballooned out to more than 5 cm in diameter before it emptied into the hernia. A 1-cm. crescentic defect along the lesser curvature of the antrum, just at the pyloric area was thought to be a small

polyp, an aberrant pancreas or an anomalous mass of rugae (A similar finding had been noted ten years previously) The prothrombin time was normal The van den Bergh reaction was 14 mg per 100 cc direct and 20 mg indirect The total protein was 6.3 gm per 100 cc, with 3.3 gm of albumin and 3.0 gm of globulin A cephalin-flocculation test was ++++ in twenty-four and forty-eight hours The cholesterol was 175 mg, and the nonprotein nitrogen 20 mg per 100 cc

An operation was performed on the ninth hospital day

DIFFERENTIAL DIAGNOSIS

DR WYMAN RICHARDSON Does anyone know whether this woman did hair dressing on the side?

DR DANIEL S ELLIS I do not know

DR RICHARDSON X-ray films revealed a hiatus hernia involving about a fourth of the stomach That is sufficient to account for the bleeding

The statement that there were large submaxillary, axillary and supraclavicular nodes is not accurate How large is "large?" Were the nodes 7 or 8 cm in diameter, were they easily palpable, and were they movable or soft and rubbery? Regarding the diagnosis in this case, one must know whether or not to take that description seriously The word "large" should make one take it seriously I should still like to know if anyone can tell me how large is "large"

DR TRACY B MALLORY Do you know, Dr Dahl?

DR LEWIS K DAHL According to Dr Richardson's classification the lymph nodes would not be regarded as large They were barely palpable

DR RICHARDSON Apparently they were not taken seriously

"The cervix was absent, and there was a firm nodule in the left vaginal vault" I do not know how to account for that either

The temperature of 100.6°F represents fever, if taken by mouth, if by rectum, it is hardly worth talking about I assume that it was rectal because most admission temperatures are

A hemoglobin of 11 gm is not normal for any patient The red-cell count is not recorded I should have liked to see the smear One can tell a great deal from a blood smear, and the observer should have noticed whether there were so-called "liver-failure cells" or "virus lymphocytes" That would be a great help in differential diagnosis

The total protein was within normal limits There was a definite increase in globulin, so that the ratio was close to 1 I should like to see the x-ray films of the stomach and cardia, to determine whether or not a carcinoma near the cardia accounted for the lymph nodes

DR STANLEY M WYMAN This is a film of the chest showing the enlarged heart, prominent chiefly in the region of the left ventricle, and the tortuous aorta The lung fields are not remarkable The

calcification described in the right upper quadrant is seen best in these two films and has the appearance of several laminated stones lying in the region of the gall bladder There is some gas close to the stones that appears to lie within a viscus I suspect that it is the duodenal cap The barium enema shows diverticulums, without significant spasm The gastrointestinal series shows the widened esophagus and the hiatus hernia from this point upward, without undue prominence of the mucosal markings but with delay in opening of the esophagus The proximal portion of the stomach is not remarkable otherwise, except for the immediate prepyloric region, where a round filling defect is seen It is present in all films and well seen in these two spot films It is a lobulated, approximately 1-cm mass, and from the record it was apparently present ten years previously, although I do not have the old film for comparison

DR RICHARDSON Is there any evidence of an obstructive lesion other than the hernia to account for the esophageal dilatation?

DR WYMAN No

DR RICHARDSON These stones are small enough to have gotten into the common duct

DR WYMAN I cannot see any others scattered around, however

DR RICHARDSON The operation might have been a biopsy of one of the nodes, a trocar biopsy of the liver, a peritoneoscopy or a laparotomy I doubt the wisdom of doing a laparotomy on a patient of this sort for the reasons presented below We know that she had gallstones, and it would be easy to come to the conclusion that she also had a stone in the common duct

Regarding the onset of the disease, it seems to me that it was not typical of simple obstructive jaundice She had both nausea and vomiting, although these symptoms lasted longer than those in the average infectious case, and she had chills sensations and may have had a fever, which does not strike me as being the typical type of Charcot fever that people sometimes have with biliary infection associated with gallstones One would expect with the onset of a gradually obstructing lesion of the biliary tract that the nausea and vomiting would have occurred later and the jaundice earlier There is some question whether the jaundice decreased, but we can take that with a grain of salt, we have no real data on that point What other evidence have we regarding the cause of this jaundice? We can assume that it was not hematogenous, because in such a case, one would expect some impression of hemolytic anemia from the smear, although I do not know that one can count on that Also, the van den Bergh reaction was not that of hematogenous jaundice, and there was bile in the urine The blood chemical findings help somewhat There was an increase in the globulin One would not expect an upset of the liver chemistry in a

straight obstructive jaundice of short duration. I have always criticized the cephalin-flocculation test, but in this case it is rather suggestive evidence of intrahepatic disease as opposed to biliary obstruction. On the basis of this evidence I shall say that the jaundice was not due to biliary obstruction by a stone or by a carcinoma of the head of the pancreas, the usual cause of biliary obstruction in people of this age, or to biliary carcinoma secondary to gallstones. The jaundice must therefore have been due to either infectious or toxic hepatitis. The reason I asked about the hair dressing is that there may be something in the material used in the so-called "cold wave" that will produce a granulopenia, and in some cases toxic hepatitis. In spite of the patient's age—infectious hepatitis seldom occurs in this age group—I believe that this disease was the most probable cause of the jaundice. Jersild* has reported from Denmark a series of cases of hepatitis occurring exclusively in women, usually after the menopause.

I shall say that this patient had infectious hepatitis, in which enlargement of the lymph nodes is not rare and may become so prominent, with such an abnormal blood picture, that the disease is considered to be infectious mononucleosis, with jaundice, rather than infectious hepatitis with lymphadenopathy. Some patients have a positive heterophil reaction, and such cases are called infectious mononucleosis with jaundice. This patient was too old for that.

Were the enlarged lymph nodes part of the infectious-hepatitis process? When I first went over the record I was going to take the nodes seriously and consider the possibility that this patient had carcinoma in the hiatus hernia or near the cardia of the stomach, metastasizing to the lymph nodes in the neck. But since no more attention was paid to them, I shall discard that diagnosis.

Were the nodes due to some form of lymphoma, with hepatic involvement? In my experience hepatic involvement with jaundice is almost always a late manifestation of this disease, and there is rarely a primary involvement of the liver by lymphoma. I recall one case, however, in which that was the cause of rapidly progressive jaundice and death, but such a course seems unlikely in the case under discussion. I must therefore put the nodes down to a probable infectious process and shall not emphasize them further. I might say parenthetically that I have not been given a report of the blood Hinton test, and with the perforated septum one must consider the possibility of syphilis. This does not sound like *hepar lobatum* or the secondary stage of syphilis, and I think that we can safely discard that diagnosis.

We must account for the pyuria and the albuminuria. There was nothing in the way of symptoms to accompany them.

DR MALLORY: Seven years before admission the blood Hinton reaction was negative.

DR RICHARDSON: That suggests that the perforated septum was not due to syphilis.

On the basis of the pyuria and the albuminuria I shall say that the patient had chronic pyelonephritis.

The description of the joint changes sounds like that of rheumatoid arthritis, with ankylosis of the left ankle. The history of rheumatic fever was not characteristic, it may have been rheumatoid arthritis.

The cardiac symptoms might be explained on the basis of a diaphragmatic hernia. There is x-ray evidence of arteriosclerosis. One would not go astray if one said that there was a certain amount of arteriosclerotic heart disease, without committing oneself further.

I can make a diagnosis of cholelithiasis without fear of contradiction. That is the only diagnosis that I am sure is correct in this case.

The hemoglobin of 11 gm is not clearly explained, and I do not know whether or not I should take it seriously. The best way to account for it is on the basis of a mild iron-deficiency anemia associated with constant slow loss of blood from the hiatus hernia, which is not rare. I shall therefore say that this patient had infectious—possibly toxic—hepatitis, chronic pyelonephritis, rheumatoid arthritis, cholelithiasis and mild arteriosclerotic heart disease.

DR ELLIS: Was the alkaline phosphatase level determined?

DR RICHARDSON: There is no record of it.

DR MALLORY: Will you tell the impression on the wards, Dr Dahl?

DR DAHL: Unfortunately I did not see this patient until after she had been operated on. There are several points that the historian omitted from the abstract that helped Dr Richardson, I believe. Dr Peterson saw her during a period when she had what he described as typical gall-bladder colic, for which she was given Demerol with complete relief. Needless to say at that time the main diagnosis was obstructive jaundice and the attack served merely to confirm that diagnosis.

DR RICHARDSON: How about the prothrombin time? Do you remember what that was?

DR DAHL: It was slightly elevated.

CLINICAL DIAGNOSIS

Infectious hepatitis
Bronchopneumonia

DR RICHARDSON'S DIAGNOSES

Infectious (?) toxic hepatitis
Cholelithiasis

*Jersild, M. Infectious hepatitis with subacute atrophy of liver epidemic in women after menopause. *New Eng J Med* 237: 8-11, 1947.

Arteriosclerotic heart disease, mild
Rheumatoid arthritis
Chronic pyelonephritis

ANATOMICAL DIAGNOSES

Acute infectious hepatitis
Bile nephrosis
Cardiac hypertrophy
Coronary sclerosis
Cholelithiasis

PATHOLOGICAL DISCUSSION

DR MALLORY The patient was explored on one of the surgical services. The gall bladder was found to contain stones and was removed. The common duct was explored, but no stones were found in it or in the cystic duct. The common duct was drained. The liver was not considered grossly abnormal, and nothing abnormal was felt in the head of the pancreas. After operation the patient was not relieved of jaundice, slowly and steadily failed, passed eventually into a cholemic state and died twenty-four days after operation. Do you care to change your diagnosis, Dr Richardson?

DR RICHARDSON Infectious hepatitis, with atrophy of the liver.

DR ELLIS Dr Richardson is a brave man to make that diagnosis in the presence of gallstones.

DR REED HARWOOD How about cinchophen poisoning?

DR MALLORY There was no history of it.

DR RICHARDSON It used to be Weldon. That is a good suggestion in a patient with known arthritis.

DR MALLORY Post-mortem examination showed a severely diseased liver. The organ was only slightly reduced in size, weighing 1600 gm, but was extremely flabby. When it was laid on the table, it settled and flattened out, unable to maintain its form. Microscopically, such livers are troublesome because there is such extensive necrosis that it is impossible to see more than the shadow outlines of pre-existing cells. It is difficult to distinguish ante-mortem from post-mortem changes. Enough could be made out, however, to say that there was fairly extensive round-cell infiltration of the portal areas and considerable ante-mortem degeneration of the liver cells, which were frequently swollen with fat vacuoles and contained large amounts of bilirubin. There is no question that acute hepatitis was present. On the histology as it stands, I do not believe that I can distinguish between the toxic and the infectious type of hepatitis. I am inclined to agree with Dr Richardson that the infectious type is more probable, since there was no history to suggest intoxication.

The other findings at autopsy were a moderately hypertrophied heart, which weighed 450 gm, with severe sclerosis of the left descending coronary artery and some narrowing of other branches, but

no areas of infarction. The serous cavities contained small to moderate amounts of fluid—a frequent finding in liver disease. These were transudates in character. There were a diverticulum of the duodenum and numerous diverticula of the sigmoid, and there was some localized endometriosis of the uterus, which probably represented the pelvic mass that was felt.

DR RICHARDSON What about the kidneys?

DR MALLORY They were enlarged and deeply bile stained and showed the picture that is described as bile nephrosis. There was no evidence of pyelonephritis.

DR WYMAN. What was the nature of the lesion in the prepyloric region?

DR MALLORY Other than the duodenal diverticulum, nothing was noted.

DR RICHARDSON Have you seen the article by Jersild?

DR MALLORY. Yes, I have.

DR RICHARDSON This case seems similar to the group that he reported. Do you think that we are going to begin to see them here?

DR MALLORY This case is entirely analogous, as I see it. There is nothing to distinguish these cases from ordinary infectious hepatitis except the epidemiologic character. They have occurred almost exclusively in women, beyond the menopause, and the mortality rate is extraordinarily high—nearly four hundred times as high as that in ordinary hepatitis.

CASE 33362

PRESENTATION OF CASE

A forty-nine-year-old man entered the hospital complaining of epigastric pain and vomiting.

For many years the patient had had symptoms of intermittent epigastric burning and gaseous eructation, usually associated with bouts of excessive eating and drinking. X-ray studies ten years prior to admission were said to have shown a duodenal ulcer. Occasionally, he vomited after excesses but was always able to control the symptoms by limiting his diet to crackers and milk for a few days. Two years before admission he had a severe attack of nonradiating epigastric pain, with vomiting, chills and fever, this lasted a few hours and was relieved permanently by a single injection of morphine. Subsequently, the symptoms were as before, although slightly more frequent. A month before entry he began having attacks of epigastric pain and vomiting that were quite persistent and recurred at weekly intervals. These were accompanied by fever and chills, but otherwise the patient felt fairly well, without malaise or nausea. The appetite remained good. There was no evidence of bleeding in the stools or vomitus.

Physical examination was negative. The patient appeared to be in good health, without acute discomfort. The abdomen was soft and nontender. The temperature, pulse, and respirations were normal. The blood pressure was 108 systolic, 70 diastolic.

Examination of the blood revealed a hemoglobin of 12 gm and a white-cell count of 11,300, with a normal differential count. The nonprotein nitrogen was 24 mg and the total protein 6.7 gm per 100 cc, the chloride was 104 milliequiv per liter.

A gastrointestinal series showed a normal esophagus. The stomach contained a rather large amount of secretion. There were a small hiatus hernia and sonic spasm in the region of the antrum. There was no evidence of a crater or filling defect in the stomach. The duodenal cap filled well, without deformity. The duodenal loop was normal.

On the fifth hospital day an exploratory laparotomy was performed. The gall bladder was considerably thickened and contained stones. A stone was also palpable in the common duct. The stomach and duodenum appeared entirely normal. The liver was thought to be rather small but not particularly abnormal in appearance. The common duct was opened and found to be dilated and surrounded by considerable inflammation. A stone the size of a large bean was removed just above the papilla. The common duct was washed out with physiologic saline solution, and the papilla dilated. The gall bladder was then removed, and a probe passed down through the stump of the cystic duct to ensure the absence of stones. A catheter was sutured into the duct. The immediate postoperative condition was good. The blood pressure and pulse were stable, but the temperature rose for a single day to 102°F. The common-duct catheter did not drain properly and was thought to be plugged. Bile seeped through a draining wick in large quantities, however. On the fifth postoperative day the patient became markedly agitated, with hallucinations lasting for approximately forty-eight hours. Barbiturates were discontinued, and he improved. On the ninth postoperative day the common-duct catheter was partially out and was removed entirely. The drain was half withdrawn. All skin sutures were taken out. The wound was clean, closed and well healed. On the following day the wound suddenly became painful and hard. When examined it was red and tender and bulged in the right end. On pressure bloody fluid was discharged. The wound was opened for about 3 cm, and a dry sponge was packed into it. Later the same day the patient felt weak and nauseated, and the bandages were found to be blood soaked. The pulse was 80, the temperature 99°F, and the blood pressure 70 systolic, 60 diastolic. An exploratory operation was done, and the bleeding was found to be due to numerous areas of oozing along the wound and the drainage tract and from

the gall-bladder-resection bed. Fibrin foam and thrombin appeared to control the bleeding.

During the following two and a half weeks the patient continued to bleed in large amounts from the wound and by rectum. He often complained of severe epigastric and shoulder pain, which was aggravated by lowering of the head of the bed. The blood pressure fell to a shock level on a few occasions. The prothrombin time, which was determined on several occasions, varied from 18 to 23 seconds (normal, 15 seconds). The platelets appeared normal. The clotting time was 4 minutes in the first tube, 5 minutes in the second tube and 6 minutes in the third tube. The bleeding time was 130 seconds. On the twenty-fifth hospital day the patient became quite jaundiced. The urine gave a +++ test for bile, with urobilinogen present up to a 1:700 dilution. The van den Bergh reaction was 8.7 mg per 100 cc direct and 11.5 mg indirect.

Throughout the course of the bleeding numerous transfusions of whole blood were given, as well as massive doses of Hykinone. Massive hemorrhages continued, however, and the patient expired on the thirty-first hospital day.

DIFFERENTIAL DIAGNOSIS

DR DANIEL S. ELLIS: So far as I can tell it is perfectly logical to explain the symptoms up to the time of operation on the basis of cholecystitis and cholelithiasis, and I seriously doubt whether the patient had ever had an ulcer. It seems to me that the decision to operate was made rather suddenly, and from the history I cannot quite figure out why, unless gallstones were visible in the films that were taken.

DR STANLEY M. WYMAN: The x-ray examination was done with the tube in position, and the film shows the hiatus hernia described. The stomach shows no gross defect. On this single film the duodenal cap extends rather posteriorly. It appears a little smaller than usual, but these spot films of the duodenum show no definite constant deformity or crater. I do not see the gallstone that Dr. Ellis is interested in on any of these films.

DR ELLIS: As usual, the x-ray films do not tell all I should like to know. The problem, as I see it, is what caused the bleeding. Obviously, the patient died of hemorrhage and cholemia, and it is up to me to explain why he was jaundiced, presumably after the stone had been removed from the common duct, and why he bled enough to cause death. It is mentioned in the early part of the history that the patient had nausea, vomiting and pain. It does not tell how much alcohol he drank. Many patients with cirrhosis of the liver bleed considerably at the time of operation. We do not get any help from the laboratory reports in making the diagnosis of cirrhosis of the liver, other than the fact that the prothrombin time apparently continued to be moderately elevated in the presence,

of massive doses of Hykinone and multiple transfusions. That leads me to believe that some process in the liver caused a failure of prothrombin synthesis and therefore resulted in inability of the blood to clot. Whether this condition in the liver existed at the time of operation or whether it developed following operation is one of the questions to which I should like to know the answer. There can be little doubt that the patient had cholecystitis and cholangitis. The attacks of pain and nausea and vomiting were associated with chills and fever. The description of the liver at the time of operation is that it was slightly small but otherwise normal. We do not have the advantage of knowing about a biopsy report or bromsulfalein test previous to operation. For the moment, I shall say that this patient had cirrhosis of the liver, which would account for the excessive bleeding following operation.

Another condition that might be considered the source of bleeding is purpura, but I can do no more than mention it as a possibility. I can find nothing in the history or in the evidence as given to prove such a diagnosis.

Amyloidosis might give rise to such bleeding but does not explain the preoperative course. We have recently had a patient who bled considerably after operation and who was later found to have amyloidosis. I certainly cannot make such a diagnosis on the basis of the information given.

Recently, there has been considerable discussion in some circles about citrate poisoning and the inability of a damaged liver to handle large amounts of citrate such as this patient might have had in repeated transfusions. I can find no material in the literature, however, that really backs up the fact that citrate poisoning can occur from faulty metabolism of the citrate breakdown to produce an increased bleeding time. I do not know how many transfusions this patient had before operation, the statement is made that he had many afterward—these, of course, were given after he started to bleed.

Was the blood from the rectum bright red or did the patient pass tarry fecal material?

DR. TRACY B. MALLORY: The record is not available, but perhaps Dr. Richardson can tell you.

DR. WYMAN RICHARDSON: The patient passed a considerable amount of obvious blood, not bright red but exactly what one would expect from gastrointestinal bleeding, that was late in the course of the disease.

DR. ELLIS: The statement was made at the time of admission that there had been no bleeding, which was first mentioned shortly before death. If this man had acute portal thrombosis he could have had bleeding into the gastrointestinal tract. This could have been due to portal back pressure or infarction of the bowel caused by retrograde thrombosis of the mesenteric veins. If he had an acute portal thrombosis, he may have had infarction of the liver, with subsequent jaundice. At least

half the cases of portal-vein thrombosis are associated with portal cirrhosis. A large number of them are due to malignant lesions in the porta hepatis. Inflammatory conditions in adjacent areas, such as cholangitis, pancreatitis and subphrenic abscess, also cause portal thrombosis. In this case something was going on under the diaphragm, for when the head of the bed was lowered the patient had pain, radiating to the shoulder—a diaphragmatic pleurisy. Whether he had a frank abscess or a collection of blood without infection, I do not know. I rather think that he had bile in the peritoneal cavity, in addition to the blood, and that the combination of the two was sufficient to cause irritation and symptoms.

From the surgical point of view I wonder why the catheter did not drain immediately after operation. I should like to believe that the liver was not manufacturing bile. On the other hand, the record mentions previous drainage through the cigarette wick and rubber drain in the abdomen, therefore, I take it that bile was leaking around the catheter. This obstruction, then, was most certainly of a mechanical nature. In view of the subsequent events it may well have been due to a blood clot. From the operative notes given it seems that thorough exploration of the common and cystic ducts had been done, and I trust the surgeon who did it. I shall therefore assume that no stones were left and that plugging of the catheter was due to a blood clot coming out of the common duct.

In summary, it seems to me that this patient died of hemorrhage and cholemia, secondary to some process in the liver. He may have had cirrhosis in addition to the cholecystitis and cholelithiasis, but I cannot do more than guess at that. I believe that the portal thrombosis after operation probably explains the subsequent events. I shall therefore say that the portal thrombosis was due to infection and cholangitis, as well as to a peritoneal inflammatory reaction caused by the presence of bile and blood in the peritoneal cavity and around the bed of the drainage.

DR. RICHARDSON: I saw the patient about three days before he died. Unfortunately, the record is not here to keep me honest, but I hope I quote myself correctly. I was asked to explain the bleeding. At that time it became somewhat apparent to me—I do not know whether it was the appearance of the man or something the family said—that he had drunk a great deal of alcohol. How much I do not know, but I should think entirely too much—that is, he drank more than would be good for you and me. I could not determine any reason for the bleeding that was compatible with the normal bleeding and clotting times. My opinion was that he had a severe hepatitis. Dr. Ellis said that cirrhotic patients bleed postoperatively, I wish he would tell me why.

DR ELLIS For two reasons — first, because the ability of the liver to form prothrombin is damaged

DR RICHARDSON This patient's prothrombin time was 23 seconds, against a normal of 19 seconds. That is not enough

DR ELLIS As a matter of fact it was 23 seconds with a control of 15 seconds, which is a little more than I should consider normal in the presence of Hykinone and transfusions, if he did not have some damage to the liver

DR RICHARDSON That level would not account for the bleeding necessarily

DA ELLIS The other reason for the hemorrhage in these cases is the increased vascularity

DR RICHARDSON It may be all right if a diseased liver is involved. That is why this patient bled — lack of fibrinogen or something that we do not know about.

DR ELLIS And also the lack of ability to form prothrombin

DR LEWIS K DAHL The patient would not have bled with this level of prothrombin

DR RICHARDSON I do not believe that the citrate theory fits this case. Diseased livers are apt to bleed, and all the tests of clotting are quite normal or sufficiently near normal not to be the cause of bleeding. I thought that this patient had hepatitis and that the surgeon had removed the gall bladder, being quite confident that this was largely a question of gallstones

CLINICAL DIAGNOSES

Acute hepatitis

Massive intraperitoneal and gastrointestinal hemorrhage

DR ELLIS'S DIAGNOSES

Acute portal thrombosis

Cholangitis

Cholemia

Massive intraperitoneal and gastrointestinal hemorrhage

ANATOMICAL DIAGNOSES

Intrahepatic cholangitis

Massive intraperitoneal and gastrointestinal hemorrhage

Gas-bacillus infection, terminal

Operation cholecystectomy or cholelithiasis, recent.

PATHOLOGICAL DISCUSSION

DR MALLORY I am not going to explain the hemorrhage any better than the clinicians have been able to do it. The liver was considerably diseased — it seemed to consist of a bag full of jelly. When touched, it quivered all over. This jelly-like substance was full of bubbles of gas developing so fast that although the bubbles could barely be seen at the beginning of the post-mortem examination, two hours later they were grossly visible. There was therefore a terminal massive gas-bacillus infection that could not have existed very long. Unfortunately, it had a marked destructive effect on the liver tissue, which again made it difficult to know what was going on before death. There was enough left, I believe, to say that this picture was definitely different from the preceding one (Case 33361). In this case the tissues of the portal areas, especially around the bile duct were massively infiltrated with polymorphonuclear leukocytes — not mononuclear cells such as one sees in infectious hepatitis. The picture was that of severe intrahepatic cholangitis. How much damage of liver cells there may have been as well, I am unable to say because of the presence of the gas-bacillus infection. The region of the common duct was carefully explored. No large vessels were found that could have served as a source of massive hemorrhage. The entire intestinal tract, from stomach to rectum, was filled with fresh blood. There were clots of blood in the gall-bladder bed. This was nearly two weeks after operation, and the blood should have been entirely dried up by that time. There was about 2500 cc. of fresh blood in the peritoneal cavity. We could not make out any definite bile staining in the peritoneal fluid.

Nothing else of importance was found.

DR ELLIS I should like to ask why operation was performed on the fifth day.

DR RICHARDSON I only saw the patient just before he died, but I know that the preoperative diagnoses were cholecystitis and cholelithiasis. He was operated on as a routine gall-bladder case.

FASHIONS IN MEDICAL WRITING

JUST as practice in the care of patients and in matters of medication and therapy change from decade to decade, so also change the customs employed in the presentation of physicians' thoughts to professional colleagues in the form of medical literature.

In the past seventy years there has been a trend in the American medical literature toward more objective factual documentation. All will agree that this has been a step forward, producing clinical articles that are based on tabulation and the case protocols of specifically identified patients rather than on vague impressions. In part, this change has sprung from the tendency of more medical investigators to receive training in fundamental scientific research. One need only look at a few of the articles, in some of the highly specialized journals to

realize that scientific material of the utmost importance is often presented in an article of one or two pages, with an accompanying table or chart. Unfortunately, however, colorful English and in triguing descriptions of clinical events have been carried away in this scientific tidal wave. Our ancestors often wrote clinical articles containing vivid language, which gave the reader a graphic and lasting picture of the clinical situation the writer had in mind, this was good teaching as well as good writing. Much of this skill has been lost, and its loss has been an aspect of the scientific trend one cannot paint a blueprint in lurid colors, and the style of Macaulay is out of place in a series of case reports. Possibly, this trend has gone too far in American medical literature. Some of the English writers at the present time — for example, Ogilvie and Gordon-Taylor — can report clinical material in a way that brings color, interest and humor to the cases.

Two other abuses that are becoming epidemic cannot be dealt with so gently. One of these is the use of what might be called the "secretarial bibliography." Certain medical authors make a specialty of this procedure. The usual practice is to write an article on some rather commonplace subject and to append thereto a bibliography of two or three hundred references.

Just what should be the significance of the bibliography in a clinical article? Is it supposed to be an encyclopedic mention of everyone who has ever thought about the subject before? Or should it represent the background of the writers themselves, who believe that the reader may use the material to his profit and edification? The latter seems to be the more reasonable choice. If one wishes to publish a review article, a long list of references is appropriate, and each bibliographic item is dealt with in detail and its contribution summarized or criticized. The insertion of half a dozen bibliographic references in the middle of a sentence — often after a single word or phrase — simply to indicate that six articles can be found in the *Quarterly Cumulative Index Medicus* leaves the reader with the conviction that the writers never read through this long bibliography before starting their work. It is common knowledge that such extensive bibliographies are often worked up by secretarial

help, this is a prostitution of the medical library and adds nothing to the medical literature. If an author wishes to include a long bibliography and does not wish to write a review article, he should not forget the usefulness of the annotated bibliography, in which a long series of bibliographic references may be mentioned and the contents briefly described so that the reader can pick and choose matters that concern him.

Another modern abuse of medical writing, even more a product of the machine age than the secretarial bibliography, is the "punch-card article" on clinical material. When anthropometric data or the distribution of age, weight and height among school children is being dealt with, the use of a punch-card system may yield material of much interest and information. When, however, a punch-card statistical device is applied to clinical material that has an extremely variable background, the data that come from the machine may have little or no meaning. The old platitude that a chain is as strong as its weakest link might be paraphrased to state that statistical information on clinical patients is of as great value as the thought that has gone into its selection. Merely to analyze a large series of tumors according to whether the patient had red hair or dark hair, large ears or small ears and did or did not smoke cigarettes adds little to knowledge, even though it yields numbers that have two significant decimal places and adapt themselves well to the drawing up of innumerable charts and graphs. As the anthropologist approaches a statistical problem, for example, measurements of head size, he puts in his punch-card system all the standard measurements of the skull that can be reproduced, these are his variables. He then uses the machine as a device for singling out which of these variables are significant in relation to racial grouping. A sick human being, however, demonstrates so many thousands of variables that it is difficult to determine which ones to study on the statistical machine. The result is that the writer or investigator puts into the machine variables that he considered significant at the outset of his investigation. The machine can then only show whether the investigator was right or wrong; it can only reflect what was going on in his mind—it can uncover no new material.

As the punch-card system becomes better known to clinical investigators it will be used more widely, with an increasing flow of articles in which the frequency of variables in the patient's constitution, diet, habit, blood chemical findings and so forth in a certain disease are analyzed. In the preparation of such an article it is always well to put each variable to the following test: "Is this a factor of established importance in the disease—one that has been known for years to affect its incidence, occurrence or outcome?" If the answer to this question is "Yes," the machine has contributed little to knowledge except for affixing the stamp of statistical approval to a previous clinical impression. If, however, the variable analyzed was previously unknown as being significantly related to the occurrence, course or mortality of the disease, this statistical device will teach the reader something of worth.

As one contemplates the volcano of medical literature erupting from the universities, clinics and laboratories of this country, one cannot but express the hope that clinical articles will be written with imagination and color, that they will give a graphic and frank picture of the problems of disease or therapy, the bad shown with the good and the poor results with the cures, and that material relating to laboratory investigations of a fundamental nature will be presented with the utmost simplicity and a minimum of confusing data, without apology or pipe-dream exploration of the future. And lastly, it is hoped that the secretarial bibliography and punch-card article will be used sparingly and to good purpose rather than as a method of showing off the thoroughness of the author's investigative devices.

HEALTH CENTERS

THE first health center in the United States, according to an analysis prepared for the Council on Medical Service of the American Medical Association by Dr. Dean F. Smiley,* was established in Philadelphia in 1912 as a child-health center. There are now at least one hundred and fifty in operation, of various types, under public or private auspices. Many of these are more than health centers con-

*Smiley, D. F. Health centers under Hospital Construction Act. *J. A. M. A.* 134:1179-1181, 1947.

cerned chiefly with health promotion, they have had added to them welfare, recreational, hospital-service and medical-service functions

A particular and urgent interest in the health center has been necessitated at this time by the passage of the Hospital Survey and Construction Act of 1946. If health centers are to be provided, it is well to know the best types to put into operation under the given circumstances

The most important needs to be met, Dr Smiley believes, are, in order of urgency, as follows: community hospitals of fifty or more beds for rural communities of 20,000 or over, community clinics of ten or more beds for rural communities of 4000 to 18,000, public-health centers to serve as headquarters for single county or multicounty public-health units, and public-health centers to serve as extensions of the single county or multicounty public-health units into the smaller communities

Dr Smiley's chief recommendations are four-fold

That only five functions (communicable-disease control, sanitation, maternal-infant-child hygiene, vital statistics and health education) be generally included under the title of public-health center as that title is used in the Hospital Survey and Construction Act of 1946

That public-health centers be established as needed and as close as is practicable to hospitals in base, intermediate, and rural areas, and that they be integral parts of base medical centers, district medical centers and community medical centers. At every level, however, the public-health center should be administratively independent of the hospital

That, in rural communities of 4000 to 18,000 in need of sick beds but not large enough to afford a fifty-bed general hospital, "community clinics" of ten to forty beds be provided by hospital authorities rather than "public-health and medical-service centers" by public-health authorities

That, in those rural communities where bed service is available in neighboring community hospitals and the urgent need is for public-health and diagnostic facilities, facilities be provided by the public-health center not only for the traditional six-point public-health service but also for

clinical laboratory service and limited x-ray service. Offices should also be included, if desired, for the part-time use of the practicing physician of the community

MASSACHUSETTS MEDICAL SOCIETY BUREAU OF CLINICAL INFORMATION

All secretaries of various medical groups, such as special societies and alumni associations, are requested to notify the Bureau of Clinical Information regarding scheduled meetings, annual dinners and so forth. If such data are on file, it is hoped that duplication of dates can be avoided

DEATHS

CUTLER — Elliott C. Cutler, M.D., of Brookline, died on August 16. He was in his sixtieth year.

Dr. Cutler received his degree from Harvard Medical School in 1913. He served in World War I with the Harvard Medical Unit and the United States Army Medical Corps. In World War II, as head of the Medical Aid Division of the Massachusetts Committee on Public Safety, he organized a system that served as a model for the rest of the country; later, he was chief consultant in surgery, European Theater of Operations, with the rank of brigadier general. He was Moseley Professor of Surgery, Harvard Medical School, and surgeon-in-chief, Peter Bent Brigham Hospital. He was a member of the American Surgical Association, Society of Clinical Surgery, New England Surgical Society, American Association for Thoracic Surgery, American Society for Clinical Investigation and American Society for Experimental Pathology, a diplomate of the American Board of Surgery and a fellow of the American College of Surgeons and the American Medical Association.

His widow, four sons and four brothers survive.

HOWE — W. Lewis Howe, M.D., of Everett, died on August 18. He was in his seventy-third year.

Dr. Howe received his degree from Tufts College Medical School in 1900. He had practiced medicine in Everett for forty-five years and was for many years a member of the School Committee and Board of Health.

His widow and three sisters survive.

WISE — John M. Wise, M.D., of Watertown, died on August 8. He was in his seventy-first year.

Dr. Wise received his degree from University of Buffalo School of Medicine in 1907. He was formerly senior physician at the Middlesex County Sanatorium and was a fellow of the American Medical Association.

His widow and a son survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

PUBLIC-HEALTH CONFERENCE

The Massachusetts Public-Health Conference will be held at the University of Massachusetts in Amherst on September 11 and 12.

The conference, sponsored by the Massachusetts Public Health Association, the University of Massachusetts and the Massachusetts Department of Public Health, is intended to stimulate interest in extending protective health services to communities that lack facilities and personnel. Health officers, milk inspectors, sanitarians, nurses, physicians,

health educators and other health workers throughout the Commonwealth are expected to attend.

Among the topics to be discussed are the following: "Bringing Health Services to Your Back Door," by Dr Haven Emerson, chairman, Committee on Local Health Units, American Public Health Association, "Functions of Health Centers," by Dr Charles F Wilensky, president of the Massachusetts Public Health Association, "Unmet Needs for Children," by Dr Lendon Snedeker, executive secretary of the Massachusetts Study of Child Health Services, "The Importance of Local Health Departments to the Nation," by Dr Herman G Hilleboe, former assistant surgeon general of the United States Public Health Service and recently appointed by Governor Dewey as Commissioner of the New York State Department of Health, and "Dollars for Health," by Dr Vlado A Getting, commissioner of the Massachusetts Department of Public Health. Special section meetings will be held for health officers, health agents, nurses and sanitarians. Governor Robert F Bradford will deliver the keynote address, "Health for Massachusetts," at the opening of the conference.

All those who are interested are invited to attend the two-day conference. Reservations for overnight accommodations may be made by writing to Professor Ralph L France, Marshall Hall, University of Massachusetts, Amherst, Massachusetts.

MISCELLANY

RADIO BROADCASTS

"The Medical Center of the Air" is continuing its series of weekly radio broadcasts every Saturday morning from 11:30 to 12:00 (EDT) over station WNAC and the Yankee Network. The programs are sponsored by the Massachusetts Memorial, Beth Israel Boston City and Peter Bent Brigham hospitals which rotate in presenting programs of medical educational interest. Specific diseases and topics of general interest are discussed. The programs are presented as a public service feature without commercial advertising.

NOTE

Dr Herbert H. Howard, of 270 Commonwealth Avenue Boston, consultant in urology at the Boston City Hospital, was recently installed as president of the American Urological Association.

CORRESPONDENCE

SCIENTIFIC EXHIBITS AT ANNUAL MEETING

To the Editor: Each year the Massachusetts Medical Society convenes not only to elect officers but also to stimulate and inform its members by means of papers and exhibits on recent medical progress. An opportunity is also given to commercial houses to exhibit their wares. This year the commercial exhibitors outdid themselves taking up the entire floor of both the ballroom and the foyer. The scientific exhibits, numbering four, were given no prominence whatsoever in the initial arrangements. Two were placed at the rear of a small blind pocket labeled "Ladies' Parlor" off the foyer. One was placed in the balcony and the fourth the Lahey Exhibit, in a corridor leading from the registration desk. Eventually the Vincent Memorial Laboratory Exhibit came to rest opposite the Lahey Exhibit. If one entered the ballroom by the main entrance, this corridor might not have been noticed at all.

One might seriously ask whether the Committee on Arrangements tried to discourage clinicians and research

laboratories from exhibiting. Certainly it is a major reflection on the Society that only four technical exhibits were entered this year, a considerable reduction from last year. The exclusion of these exhibits from the ball room or foyer floor, and their random placement in a corridor, a ladies' parlor and a balcony contributed nothing toward encouraging further exhibitors for another year. These exhibits take much time to prepare. That they appear to have been completely ignored in deference to space allotment for commercial firms forces one to conclude that the time taken in their preparation was out of all proportion to the value accredited them by the Committee on Arrangements.

The outlook for next year would be improved by an emphatic statement by this committee that due prominence and consideration would be given the scientific exhibits in planning for 1948.

JOE V MEIGS, M.D.
Chief Vincent Memorial Hospital

Massachusetts General Hospital
Boston 14

* * *

Dr Meigs's letter was referred to Dr George G Bailey, chairman of the Committee on Arrangements for 1947-1948. His reply is as follows:

To the Editor: Thank you for calling attention to Dr Joe V Meigs's letter regarding the scientific exhibits at the last annual meeting of the Massachusetts Medical Society. The Committee on Arrangements sincerely regrets that Dr Meigs was dissatisfied with the scarcity and location of the scientific exhibits.

At a recent meeting of the committee the entire subject of exhibits was discussed. It was decided that, as a working basis for next year, ten booths would be assigned for scientific exhibits and that the remainder would be available for commercial exhibits. It may seem that this is a relatively small number to be assigned for scientific exhibits but it is a fact that in the past few years it has been difficult to persuade hospitals and physicians to prepare exhibits for display at the annual meeting. It was further agreed that an effort would be made to solicit exhibits from leading hospitals and clinics as well as from individual clinicians for the meeting. Also a more central location will be assigned to the scientific exhibits. The committee would appreciate hearing from any hospitals or individuals interested in arranging an exhibit for next year's meeting. It would be most helpful if definite plans of any prospective exhibitor could be in the hands of the committee by November 1.

GEORGE G BAILEY M.D.
Chairman Committee on Arrangements

BOOK REVIEWS

Health Insurance in the United States. By Nathan Sinai, Dr P.H. Odin W Anderson and Melvin L. Dollar. Studies of the Committee on Medicine and the Changing Order. New York Academy of Medicine. 8" cloth 115 pp. New York: The Commonwealth Fund 1946. \$1.50.

This survey is confined to voluntary medical insurance because compulsory medical insurance, except workmen's compensation in a small way has not yet been established in the United States. The history of the health-insurance movement is covered for the period from 1910 to the beginning of World War II. The various group plans, such as Blue Cross, medical society industrial and labor union insurance, federal co-operatives and commercial accident and health insurance are briefly discussed. The attitudes and objectives of the various medical societies including the American Medical Association, the federal departments represented by the Public Health Service and the Social Security Board, labor public enterprise and the general public are fully analyzed and enabling legislation for voluntary plans since 1900 is reviewed. It is stated that the enrollment in nonprofit hospital-service groups increased from 2000 in 1933 to 20,000,000 in eighty seven plans in 1946.

A cumulative summary of hospital and medical acts by states shows that one state, New York had enabling legislation — a hospital act — in 1934 and that a total of thirty-five states had hospital acts and twenty-five had medical acts in 1945. The greatest increase in legislation took place in 1939 when fourteen states passed hospital acts and six

states medical acts. In 1945 there was renewed activity when eleven states passed medical acts, and two states hospital acts. Twenty-five of the thirty-five states have both hospital and medical acts. Massachusetts passed a hospital act in 1936 and a medical act in 1941.

The survey concludes with a review of the characteristic features of voluntary plans and a discussion of the problems presented by such plans, as well as the present status of the health-insurance movement. This monograph should be in all medical and public libraries.

Psychiatric Interviews with Children. Edited by Helen L. Witmer. 8°, cloth, 443 pp. New York: The Commonwealth Fund, 1946. \$4.50.

This book is well written and well published. The text is divided into three parts. In an introduction the author gives a concise and clear account of the nature of child guidance, its history and the purpose and peculiarities of this type of social psychiatry, in which physician and social workers form a perfect team and the patient is considered a part of the family rather than an isolated subject. The brief remarks about psychoneuroses and social implications are sound and up to date, utilizing the newest development of psychodynamic psychiatry without loading the text with psychoanalytic terms that may be not acceptable to everyone. The main part of the book consists of the presentation of ten actual cases studied by a number of therapists, either psychiatrists or psychologists. The clear discussion and presentation of the various interviews with the reactions of the patient and the comments of the therapist give an accurate insight into the proceedings, interpretations and therapeutic dynamics. This volume is valuable because it limits theory to a minimum and presents the actual course of interviews—a procedure that any student of psychiatry has rarely an opportunity to follow except with his own cases.

Myasthenia Gravis. By Dr. Adalberto R. Goni. Translated by Georgianna Simmons Gittinger. 8°, cloth, 112 pp., with 10 illustrations. Baltimore: Williams and Wilkins Company, 1946. Free.

This book, when published in Portuguese, was the first monograph on the subject of myasthenia gravis to appear in over twenty-five years. It thus received a warm welcome, and an English translation was much desired by neurologists and others working in the field. The author has had considerable practical experience and is fully acquainted with the current literature up to 1943. Thirteen case histories of typical examples of myasthenia gravis are presented.

The Modern Treatment of Diabetes Mellitus Including practical procedures and precautionary measures. By Williams S. Collens, M.D., and Louis C. Boas, M.D. 8°, cloth, 514 pp., with 195 illustrations. Springfield, Illinois: Charles C. Thomas, 1946. \$8.50.

In this excellent treatise on the management of diabetes and its complications, the authors discuss the practical aspects of the subject in an authoritative fashion. Except for the first chapter, which gives a historical account of diabetes and the discovery of insulin, there is relatively little in the book regarding the incidence, etiologic factors, pathologic physiology and pathology of diabetes, as stated in the opening paragraph of the volume.

It is refreshing to note that the authors obviously believe in the careful control of diabetes. Their sensible recommendations concerning treatment should help to counteract the teaching heard so much in recent years regarding the supposed harmlessness of hyperglycemia and glycosuria.

The critical reader with a special interest in diabetes will find various points with which he may not agree. On Page 48 the fasting blood sugar is mentioned prominently as a diagnostic step, and it is implied that if this determination is normal, one should proceed to a formal glucose-tolerance test. To the reviewer, this is too frequent a tendency. Physicians generally should make more use of urine and blood sugar tests done approximately an hour after a meal as a diagnostic step. Often, one may thereby avoid subjecting a patient needlessly to a glucose-tolerance test. Collens and Boas discuss the Exton-Rose test without critical comment, whereas it is fair to state that, with greater usage, it has

lost rather than gained in favor with many clinicians. On Page 52 it is observed that fructose produces a characteristic osazone with phenylhydrazine. The fact is that fructosazone is indistinguishable from glucosazone and that methyl-phenylhydrazine must be used for differentiation.

The treatment of the individual case is discussed under eight headings, with a chapter devoted to each, as follows: the obese patient with mild diabetes, the patient of normal weight with mild diabetes, the undernourished patient with mild diabetes, moderately severe diabetes, severe diabetes without ketosis, severe diabetes with ketonuria without acidosis and with ketosis (compensated acidosis), diabetes with clinical acidosis, and the diabetic patient in coma. This makes for a logical, orderly presentation of material but tends to burden the reader with detail and makes treatment seem unduly complicated.

In Chapter XIII, the authors recommend glucose intravenously in the treatment of diabetic coma, its use in the first few hours of treatment is considered undesirable and even harmful by certain clinicians. The doses of insulin recommended (page 205) are relatively small, and many would consider them incapable of achieving maximal success.

From the discussion of hepatomegaly in juvenile diabetes (page 246) it might be inferred that the enlargement of the liver seen in the untreated or poorly treated patient is due chiefly to lack of choline or lipocaine or related substances. Actually, in human patients, hepatomegaly is almost invariably abolished when the diabetic condition is brought under control with protamine-zinc insulin without the aid of special lipotropic preparations.

The book is well printed on good paper and is easy to read. Illustrations, some of which are in color, contribute greatly to the value and appearance of the volume. In the fly on the front cover is included a "Collens Diet Calculator."

Diabetes: A concise presentation. By Henry J. John, M.D. 8°, cloth, 300 pp., with 74 charts and 44 tables. St. Louis: C. V. Mosby Company, 1946. \$3.25.

This volume represents the honest and serious attempt of a clinician with a wide experience in diabetes to set forth in concise form the principles of diagnosis and treatment that he has found useful. A good deal of the material has appeared previously in articles published in medical journals, chiefly between 1929 and 1935. Consequently, the monograph is limited almost entirely to the views of the author and in some respects lacks freshness, breadth and scope of presentation.

The author is to be commended on his interest in the prevention of diabetes. He reasons that if a temporary or prediabetic state can be treated successfully in experimental animals (as in the early stages of diabetes following the injection of anterior pituitary extract), it is conceivable that the same situation may apply in human beings. Despite the inadequacy of present knowledge, the approach of the author is sound and forward-looking.

Dr. John, having had much experience with glucose-tolerance tests and their interpretation, devotes considerable space to this subject. Although there will not be general agreement regarding diagnostic standards, his recommendations are fair and safe.

The author believes that infection must be assigned a causative role in the etiology of diabetes in children. This point is debatable, and there is much evidence to the contrary. Acute infections are frequent in early life, and yet diabetes only rarely has its onset in childhood. Dr. John is one of the pioneers in the establishment of summer camps for diabetic children and writes instructively of this matter.

In a chapter on pregnancy and diabetes much space is taken up with a discussion of the diagnosis of melituria in pregnancy, and little attention is given to the all-important problem of obtaining live babies. No mention is made of the recent phenomenal success attained by the careful and continuous observation of diabetic women during pregnancy and their treatment with large doses of estrogen and progesterone.

One chapter is composed of brief paragraphs presenting some "do's" and "don't's." The advice given is practical and sensible.

This small volume contains a great deal of practical information and can be read with profit by practitioners and those with a special interest in diabetes. It cannot be con-

considered a complete monograph on the subject. It is unfortunate that, presumably owing to shortages, an inferior paper was used in the printing.

Adolescent Sterility. A study in the comparative physiology of the infecundity of the adolescent organism in mammals and man. By M. F. Ashley Montague. 8 cloth 148 pp with 33 tables. Springfield Illinois Charles C Thomas, 1946 \$3.50

The question that the author considers is: What, if any interval of time normally elapses between the appearance of the first menstruation, the menarche and the ability to conceive and carry a fetus to term? It is pointed out that the first observers to draw attention to the phenomenon of the infertility of adolescent human females were ethnologists working with tribes in Melanesia, New Guinea, South Africa, the Philippines and other areas. In such simple societies the infertility could not be explained by contraception, early sexual life or free mixing of lovers. The author then presents evidence for the presence of adolescent sterility in lower mammals, such as the mouse and the cow. In the Rhesus monkey the adolescent period is marked by the slow development of two primary phases that of puberty which begins with the menarche, and that of nubility the period at which the female becomes capable of procreation. The work of Allen, Hartman and Corner had already shown that the early menstruation of the female Rhesus monkey is normally incapable of ovulation. The chimpanzee a close relative of man, is in most cases normally incapable of conceiving until some appreciable time from the establishment of the menarche. In a chapter on adolescent sterility in man the author gives many tables of the menarche-conception interval. The adolescent sterility in the human female is up to the age of about twenty three years.

The book is written in readable style and has an excellent bibliography. Physicians, students of growth physiologists, psychologists, anthropologists and educators will find this volume worthy of careful study.

Urgent Surgery. Edited by Julius L. Sprack. M.D. Vol. 1. 8th cloth, 714 pp with 244 illustrations. Springfield, Illinois: Charles C. Thomas, 1946 \$10.00.

The editor points out in the preface that the scope of emergency surgery has been greatly widened within recent years. Today, competent surgeons working with adequate facilities are available in many rural communities that were formerly without such services, and the problem has changed from what must be done in a few minutes to what should be done within a few hours or days. For this reason the editor has chosen the title "Urgent Surgery" for this book rather than the more frequently used term "Emergency Surgery".

The eighteen chapters have been written by eight surgeons some of them specialists outside this country. Twelve chapters were written by the editor and another was revised by him. The first five chapters, which deal with transfusion, infusion, shock, anesthesia and laparotomy incisions are in general well written, reflecting the considerable experience of the authors. It seemed to the reviewer that in many places greater use could have been made of the many valuable lessons learned from the military surgery of the recent war, such as the value of blood over plasma in the treatment of shock, the use of blood in the treatment of extensive burns, the advantages of Pentothal over Evipal Sodium, the usefulness of a median or paramedian incision rather than a transverse incision when the extent of the intra-abdominal disease is unknown and the treatment of perforating wounds of the rectum.

The chapter on the liver and bile ducts by Dr. Prohm is particularly comprehensive. Many surgeons might disagree with his emphasis on the value of electrocoagulation of the gall bladder, but in all probability in his hands at least, it affords a satisfactory way of dealing with the acutely inflamed gall bladder. The chapter is long but interesting throughout and would well repay reading by anyone interested in the surgery of the liver or biliary tract. Dr. Warren Cole has written an excellent chapter on the urgent surgery of the pancreas, and as is found throughout the book, many surgical problems are considered that are ordinarily not included in works on emergency surgery.

A thorough review of the problem of intestinal obstruction by Dr. John R. Paine if carefully read, should help to correct some of the misuse of the nonoperative treatment of intestinal obstruction. The chapters on stomach surgery, congenital stenosis of the pylorus, appendicitis and urgent intestinal surgery in infants written by the editor, are extremely good and together with those previously mentioned and others, form a volume on urgent surgery that is both practical and comprehensive. There is an extensive bibliography at the end of each chapter and the book is well illustrated.

Diagnosis and Treatment of Menstrual Disorders and Sterility. By Charles Mazer, M.D., and S. Leon Israel, M.D. Second edition, revised and enlarged. 8th cloth, 570 pp., with 133 illustrations. New York: Paul B. Hoeber, Incorporated, 1946 \$7.50.

The first edition of this book, which was prepared with the family physician in mind, was well received. The second edition, which has been revised extensively and which brings the important subjects of menstrual disorders and sterility up to date, is written to serve as a guide to the general practitioner of medicine and to the medical student. There is much in the book, however, of considerable value to the specialist in gynecology and obstetrics.

The first chapter deals with the pituitary gland, and the second with the ovary. The effect of estrogen on the normal menstrual cycle, on uterine mobility on the fallopian tubes on the vesical sphincter on the anterior hypophysis, on the ovary on the breasts on libido and on the central nervous system as well as the constitutional effects, are discussed. The relative potencies of the several estrogens in terms of rat units are given in table form. The second portion of this chapter deals with the corpus luteum hormone progesterone. Puberty in the female is taken up extensively in the third chapter. The normal menstrual cycle forms the subject matter of another chapter, this cycle being divided into the following phases: the menstruating or discharging phase, the proliferative estrogen or preovulatory phase and the secretory progesterone or postovulatory phase. Each is well described and illustrated, and the photomicrographs are well chosen and executed. The hormone balance of the normal menstrual cycle is considered. Abnormal manifestations of the menstrual cycle: dysmenorrhea, premenstrual tension, menstrual migraine, abnormal breast hyperplasia, cyclic intermenstrual pain and vicarious menstruation are covered. Twenty-eight pages are devoted to dysmenorrhea; this subject is thoroughly elaborated on and the treatment, both surgical and nonsurgical, is considered. Amenorrhea and hypomenorrhea are reviewed and three types of hypomenorrhea are described: the normal, the cyclical and the uterine. The treatment of uterine bleeding—of both systemic and organic origin from such lesions as carcinoma of the cervix, chorioepithelioma, cervical polyps, malignant tumors of the ovary, pelvic inflammatory disease and endometriosis—is well presented. The phrase "dysfunctional uterine bleeding" describes the menorrhagia or metrorrhagia caused by impairment of the endocrine factors that normally control the menstrual function more accurately than the more frequently employed term "functional uterine bleeding". The treatment of dysfunctional uterine bleeding of puberty, the childbearing age and premenopausal and postmenopausal bleeding are stressed.

Nearly a quarter of the book concerns the problem of sterility; this condition being discussed under the following headings: general considerations, the influence of gross pelvic lesions on fertility, the factor of insemination of the cervix, the tubal factor in sterility and the endocrine factors in sterility of the female. The male factor in barren marriages and artificial insemination are also mentioned, and the well prepared contribution on the diagnosis and treatment of male sterility by Dr. Charles W. Charney adds to the value of the book.

Chapters on the analysis of 695 cases of primary and secondary sterility and on relative sterility follow. A bibliography containing the important contributions to each subject is appended to each chapter, and an appendix containing the commercially available standardized endocrine products completes the volume.

The second edition of this well written book will prove of value to the specialist as well as to the general practitioner and the medical student.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

A Textbook of Pathology. By E. T. Bell, M.D., professor of pathology, University of Minnesota Medical School. Contributors: B. J. Clawson, M.D., professor of pathology, University of Minnesota Medical School, and J. S. McCarty, M.D., associate professor of pathology, University of Minnesota Medical School. Sixth edition, enlarged and thoroughly revised. 8°, cloth, 910 pp., with 500 illustrations and 4 color plates. Philadelphia: Lea and Febiger, 1947. \$10.00.

This textbook has been designed for the use of students during their clinical training and as a reference source for the practicing physician. The number of editions vouches for the popularity and soundness of the book, which was first published in 1930.

This edition has been revised in the light of current knowledge, and much new material has been added, especially on the vitamin deficiencies and tropical diseases. The number of illustrations has been increased, and a list of carefully chosen references is appended to each chapter. The volume is well published in every way.

Speech and Human Relations: An approach to the physical and psychological factors involved in effective oral communication. By Joseph G. Brin, Ph.D., director, Office of Speech Counseling, Boston University. With a foreword by Frederick C. Packard, Jr., associate professor of public speaking, Harvard University. 8°, cloth, 166 pp. Boston: Bruce Humphries, Incorporated, 1946. \$2.50.

Professor Brin has written, in a simple manner, a practical handbook for persons called on to make public addresses. He does not give hard-and-fast rules, but discusses the necessary factors leading to a good speechmaking personality. Chapter twenty-one, consisting of one page, is valuable, since it lists in tabular form the virtues and vices of good speech form. The small volume is well published and should prove useful to persons called on to make public appearances.

A Textbook of Medicine. Edited by Russell L. Cecil, M.D., Sc.D., professor of clinical medicine, Cornell University Medical College, consulting physician, New York and Veterans hospitals, and visiting physician, Bellevue Hospital. With the assistance of Walsh McDermott, M.D., associate professor of medicine, Cornell University Medical College, and Harold G. Wolff, M.D., associate professor of neurology, Cornell University Medical College. Seventh edition. 4°, cloth, 1730 pp., with 244 illustrations. Philadelphia: W. B. Saunders Company, 1947. \$10.00.

This standard textbook, first published in 1927 and revised every three or four years, has, despite the limitations of the war years, been brought up to date in this new edition. The work is the joint effort of a hundred and sixty-two American physicians who are acknowledged authorities in their special fields of medicine. Twelve new authors have written sixteen articles on subjects not contained in the previous edition, including deficiencies of vitamins A, E and K, hypervitaminosis, drug allergy, marijuana intoxication, porphyria, acrodynia, narcolepsy, headache, psychosomatic medicine, hemifacial spasm, diphtheritic polyneuritis, the hemoglobinurias and blackwater fever. Because of the death or retirement of a number of authors fifty-three subjects have been rewritten by new authors. All contributions are signed. Selected references are appended to each subject. The work has been kept in one volume by the use of a double-column format and a light paper. The type and printing are good, but if the material is increased in subsequent editions a two-volume setup, using heavier paper, should be seriously considered. The light paper used in this edition will not stand hard usage. The book should prove useful to physicians and is recommended for all medical libraries.

Diseases of Metabolism: Detailed methods of diagnosis and treatment. Edited by Garfield G. Duncan, M.D., director, Medical Division, Pennsylvania Hospital, and clinical professor of medicine, Jefferson Medical College, Philadelphia. Second edition. 8°, cloth, 1045 pp., with 167 illustrations. Philadelphia: W. B. Saunders Company, 1947. \$12.00.

This standard text, first published in 1942, has been revised and brought up to date. It is the work of twenty-one recognized authorities in their respective fields. No material has been added, including a discussion of all forms of diabetes. The chapter on nutritional and metabolic aspects of disorders of the blood has been rewritten in the light of the broadening knowledge in this field. The vitamins and known clinical value are dealt with in detail, and folic acid and the *Lactobacillus casei* factor are considered in relation to nutrition and metabolism. The lists of selected references appended to the chapters have been expanded but have not been made comprehensive. The book is well published in every way. It should be in the libraries of clinicians and all medical libraries.

NOTICES

NORFOLK DISTRICT MEDICAL SOCIETY

The first 1947-1948 meeting of the Norfolk District Medical Society will be held at 8:00 p.m. on Tuesday, September 23, at the Boston Medical Library, 8 Fenway, Boston, entitled "Boston University Night." The program will consist of five papers of general interest by members of the faculty of Boston University School of Medicine.

PROGRAM

"Boston University School of Medicine: A brief account of stock." James M. Faulkner, dean and professor of clinical medicine.

"The Clinical Use of Benadryl and Pyribenzamine." Francis C. Lowell, associate professor of medicine, physician, Massachusetts Memorial Hospitals, member, Evans Memorial.

The anti-histamine activity of Benadryl and Pyribenzamine will be discussed, together with the relative merits of these two drugs in the treatment of urticaria, hay fever and other allergic conditions.

"Surgical Management of Carcinoma of the Esophagus and Cardiac End of the Stomach." John W. Stedder, assistant professor of thoracic surgery, visiting surgeon, Massachusetts Memorial Hospitals.

This paper is based on operative experience with approximately 90 cases. It concerns itself particularly with newer developments in diagnosis and surgical care and consequent improvement in end results.

"Folic Acid: Its value and its shortcomings." Joseph F. Ross, associate professor of medicine, physician, Massachusetts Memorial Hospitals, member, Evans Memorial.

Folic acid in oral doses of 1.25 to 15 mg. daily is capable of inducing and maintaining hematologic remissions in patients with pernicious anemia. There is evidence that better blood levels may be maintained with a combination of folic acid by mouth and liver extract by injection than with either medication alone. Folic acid will not prevent the development or progression of subacute combined degeneration in patients with pernicious anemia. Large daily doses actually appear to predispose to subacute combined degeneration, and to cause its progression after liver extract therapy is started. It is possible that large doses of synthetic folic acid may interfere with the metabolism of glutamic acid by the central nervous system.

"Physiological Aspects of Surgery of the Autonomic Nervous System." Reginald H. Smithwick, professor of surgery, surgeon-in-chief, Massachusetts Memorial Hospitals.

Surgery of the autonomic nervous system will be discussed from a physiologic viewpoint, with particular reference to methods of study and the nature of the therapeutic effect.

All physicians and medical students are invited to attend. A collation will be served.

FROSTBITE*

Physiology, Pathology and Therapy

KURT LANGE, M.D.,† DAVID WEINER, M.D.,‡ AND LINN J. BOYD, M.D.§

NEW YORK CITY

THE origin of gangrene subsequent to exposure to cold air or contact cooling has found the most diversified explanations. The general trend of opinions seems to have two different directions

seems to believe that injury to muscles and other tissues is subsequent to the damage of nerve fibers, which represents the main feature of the disease. Lewis and Love² went so far as to attribute most

FIGURE 1 Photomicrograph (x110) of Tissue from an Untreated Rabbit Two Days after Exposure

Note the interstitial edema and leukocytic infiltration. All vessels are filled with red-cell masses

One group, under the leadership of Blackwood¹ and Ungley and his collaborators,³ attributes most of the damage to a peripheral vasoculopathy and

of the damage following frostbite to the bursting of individual cell membranes by the formation of ice crystals. Stimulated by the early studies of Rotnes and Kreyberg,⁴ another group, consisting of Greene,⁵ Siegmund⁶ and Friedman,⁷ regards the formation of "thrombi" as the cause of gangrene.

In World War II the casualties due to frostbite were exceedingly numerous. All armies were concerned with this problem, and the number of cases was greatly increased by the severe exposures encountered in high-altitude flying.⁸ Damage to the extremities with subsequent gangrene was frequent, and death due to so-called "shock" from

*From the Department of Medicine, New York Medical College, Flower and Fifth Avenue Hospitals, and the Research Unit, Metropolitan Hospital.

This study was aided by grants from the John and Mary R. Markle Foundation and by contracts between the Council on Medical Research of the Office of Scientific Research and Development and the Research and Development Board of the Office of the Surgeon General of the United States Army and the New York Medical College.

†Assistant professor of clinical medicine, New York Medical College, Flower and Fifth Avenue Hospitals; associate visiting physician, Metropolitan Hospital.

§Professor of medicine and pharmacology, New York Medical College, Flower and Fifth Avenue Hospitals; director of medicine, Metropolitan Hospital.

laries, forming sludge that contains some platelets but little fibrin. These occlusive red-cell masses are not true fibrin thrombi but should be called "agglutinative thrombi"¹² (Fig 1). * Three to eight days after exposure these agglutinative thrombi start to undergo hyalinization, resulting in completely hyalinized occlusive masses (Fig 2).

It is interesting to note that, in accordance with the observation of Siegmund,⁶ the protein content of all blisters examined while still in the liquid state

since some of the damage to muscles and nerves seems to be due to interstitial fibrin deposition leading to fibrosis, it appeared interesting to determine whether heparinization would interrupt the chain of events.

Twenty-one rabbits, exposed to cold by immersion of one of their hind legs in alcohol at -30°C for thirty minutes, were heparinized intravenously for five or six days after exposure, the clotting time being kept between 30 and 60 minutes (Lee-White

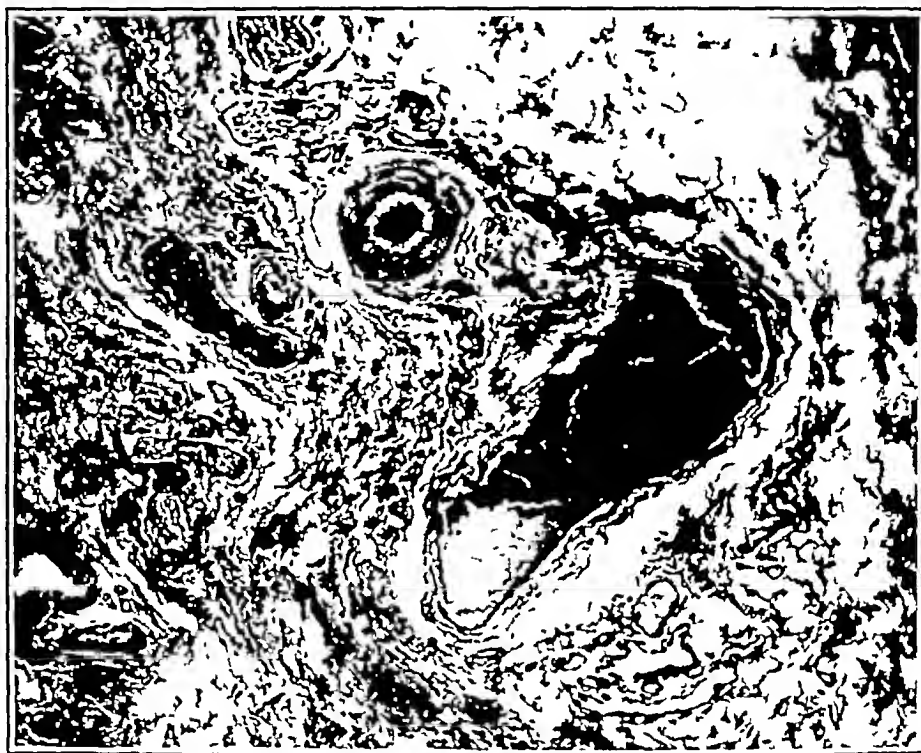

FIGURE 5 Photomicrograph ($\times 110$) of Tissue from a Heparinized Rabbit Four Days after Exposure
The blood vessels are empty or filled with normal content

was almost identical with the plasma protein content of the subject. Within twenty-four to forty-eight hours a dense fibrin clot was formed in every blister. It may be assumed that the same process takes place in the interstitial space and thus gives rise to the subsequent fibrosis and collagenous deposition noted in histologic sections, a process described by Rémy and Thérèse¹³ as "lardaceous inflammation." Many lymphatic vessels also show clogging with fibrin deposition (Fig 3). All this can be attributed to the tremendously increased capillary permeability.¹⁴

THERAPY

Since the gangrene subsequent to frostbite is due to the occlusive red-cell sludge in the capillaries and

*We are indebted to Major Nathan B. Friedman at the Army Institute of Pathology, Washington, D. C., for permitting us to use the photomicrographs that resulted from our collaboration.

method). Eighteen of the animals escaped gangrene completely, whereas 3 showed some surface lesions without loss of the limb. Twenty control animals, exposed in the same way but not heparinized, lost their legs by complete gangrene, including the bone. These animals showed dry gangrene with spontaneous self-amputation (Fig 4). Except for sterile dressings no surgical intervention was necessary in any of the animals. These findings, together with experience in 14 human patients with frostbite, treated before the introduction of heparin therapy, convinced us that an extremely conservative approach is indicated so far as amputations are concerned. Self-demarcation and the astounding recuperative power of frostbitten tissue force one to assume an attitude entirely different from that in cases of gangrene due to arteriosclerotic vascular disease.¹⁴ Histologic examinations of the exposed

legs of the heparinized animals reveal that the red-cell conglomerates, regularly found in all smaller vessels of nonheparinized exposed animals, are missing.¹² The vessels are found empty or with a normal content of cells and plasma (Fig 5). Since swelling and increased permeability, as evidenced by fluorescein tests, are observed to the same extent in heparinized as in untreated animals it must be assumed that the increased permeability leads to the accumulation of the red cells by stranding but that they cannot stick together if heparin is present in the blood stream.

A group of 8 volunteers who were undergoing treatment for subacute bacterial endocarditis at the Jewish Hospital of Brooklyn were put at our disposal through the kindness of Dr Leo Loewe.¹⁴ In 4 the frostbite was accomplished by means of a porcelain crucible filled with dry ice and applied without pressure to the skin of the lateral aspect of the upper arm for ten minutes. An area about 2 cm in diameter came in contact with the skin, which attained a temperature of about -22°C . Heparinization was started immediately after exposure. One volunteer served as a control. The others were subjected to local refrigeration in the same manner but for two exposures of thirty minutes each. The initial or control exposure was permitted to develop for six days before the second frostbite was induced, immediately followed by subcutaneous injection of heparin in Pitkin menstruum.* The clotting time in the treated cases was kept between 25 and 60 minutes. All adequately treated lesions escaped deeper injuries, whereas the control subjects showed areas of central necrosis approximately 1 cm in diameter and varying from 3 to 5 mm in depth.

A second group, consisting of 4 volunteers (conscientious objectors†), was subjected to freezing of an area 3.5 cm in diameter for thirty minutes by means of beakers filled with dry ice. Each volunteer received at least four exposures, including an untreated control, immediate heparinization for six days subsequent to exposure, heparinization for six days after an initial delay of twenty-four hours and heparinization for six days after an initial delay of twenty-four hours during which the exposed part was kept cool by means of an icebag applied to the lesion without pressure, to check on the validity of the concept that cooling subsequent to frostbite improves the course.¹⁶

The results were similar in all the volunteers. The untreated exposure led to gangrene. Immediate heparinization lasting six days prevented gangrene. Heparinization after a twenty-four-hour delay at room temperature gave almost as good a result as

immediate heparinization. Cooling in the interim produced the poorest results (Fig 6). Blister formation, which takes place rapidly in all exposed areas, is prevented in lesions kept cool after exposure. Immediately after the ice bag has been removed, however, the blisters arise rapidly and are even larger than those in the control lesions. This delay in the appearance of the blister may have led

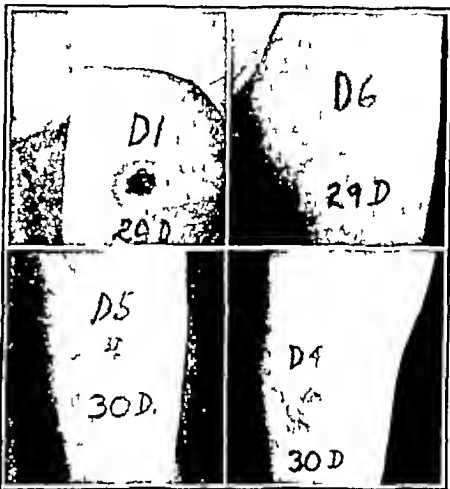

FIGURE 6. Photographs of Skin Lesions on Leg, following Exposure to a Beaker Filled with Dry Ice.

The two upper photographs, taken twenty-nine days after exposure, show two lesions in a volunteer, with the first (left) the subject received no treatment, and with the second (right) the subject was heparinized immediately and for six days after exposure. The lower ones, taken thirty days after exposure, show two other lesions in the same volunteer with the first (left) the subject was heparinized beginning twenty-four hours after exposure for six days and with the second (right) the subject was treated in the same way except that the area was cooled during the twenty-four hours after exposure.

to the belief that cooling after exposure to low temperatures is beneficial.

The blister content in all heparinized patients stayed liquid throughout. No clot formation was noticed. If the blister did not rupture in the initial phase of marked tension its content was slowly resorbed, a loose shriveled piece of skin remaining on the exposed spot. The fact that heparinization keeps the interstitial fluid, with all its constituents, resorbable is of importance in the prevention of subsequent fibrosis and collagen replacement.

A third group of 3 volunteers (conscientious objectors) was subjected to freezing of an area 5 cm in diameter by means of a metal capsule kept at -30°C . for thirty minutes. Each volunteer received at least five exposures that subsequently

*We have abandoned the use of heparin in Pitkin menstruum because of the great pain that accompanies the deposition. In animal experiments large hematomas were noted at the point of the second and subsequent injections that lead to exsanguination of the animals. In the animals, doses were used that were just sufficient to keep the clotting time for twenty-four hours between 30 and 60 minutes.

†Made available by Selective Service.

received, respectively, no treatment, warming for twenty-four hours after exposure but no heparinization, immediate heparinization for seven days subsequent to exposure, heparinization for seven days after an initial delay of twenty-four hours and heparinization for seven days after an initial delay of twenty-four hours during which the exposed part was warmed by an electric heating pad. The results were similar to those in the previous group. The untreated exposure led to gangrene, warming without heparinization made the gangrene more extensive, immediate heparinization prevented gangrene

It was conspicuous in all the volunteers that the individual reaction to a standard exposure varied widely but was rather constant in the same subject. An exposure that consistently led to extensive gangrene of the entire exposed area in one volunteer failed to produce any tissue breakdown on repeated attempts in another. It may thus be possible to screen persons with an unusually high sensitivity to cold by means of standard test procedures.

The heparinization in the last two groups and in the following cases was carried out by intra

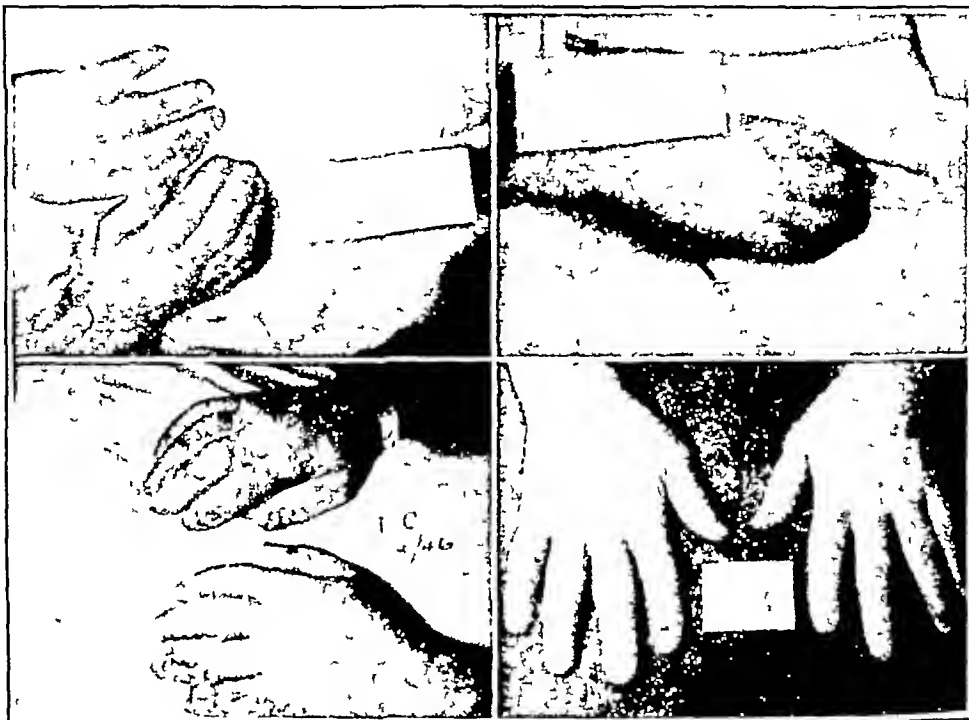

FIGURE 7 Photographs of Hands That Were Exposed to a Temperature of 14 to 18°F for Twelve Hours

The upper left photograph, taken six hours after exposure, shows edema and hemorrhagic blistering. The upper right, taken twenty-four hours after exposure, showed marked edema and large blisters. The lower left, taken four days after exposure and during heparinization, shows considerable edema but there was evidence of good circulation beneath the blisters. The lower right, taken three weeks after exposure, shows a complete return to normal, except for loss of the nails.

completely, and heparinization after twenty-four hours gave almost as good a result as immediate heparinization. Warming in the interval before heparinization produced a lesion that was almost as large as the untreated control lesion, although not so severe as the lesion with interval cooling in the previous group of volunteers. Although loss of tissue was completely prevented in the cases with early heparinization all sensation was lost for at least three months. The same loss of sensation occurred in the treated animals with complete maintenance of tissue. The motor disturbances in these animals, as demonstrated by dragging of the leg, disappeared in four to six weeks.

venous drip. Approximately 300 mg of heparin in 2000 cc of physiologic saline solution per twenty-four hours was given at the rate of approximately 20 to 25 drops per minute. The clotting time (Lee-White method) was kept between 30 and 60 minutes and was checked every twelve hours. No untoward effects were seen in any of the cases treated by this method. Whenever possible, a vein on the middle part of the extensor surface of the forearm was used for the administration of the intravenous drip. The needle and a wide loop of the connecting tubing were fixed to the forearm by adhesive tape. No splint was used at any time, the patient thus being permitted to employ the

arm freely for eating and writing. The patient was even permitted to get off the bed while it was being made. In no case was it necessary to insert the needle more than twice.

Two actual cases of severe frostbite were treated by this method.¹⁷ One patient had been exposed to a temperature of 12 to 13°F for eight hours while lying with bare hands motionless on the pavement. The other had been exposed to a temperature between 14 and 18°F while lying motionless with bare hands on the pavement for twelve hours. Both patients had severe degrees of hemorrhagic blistering within twenty-four hours of exposure. Heparinization was started six and ten hours respectively after the exposures and carried out according to the method mentioned above for seven and five days respectively. The hands were dressed under sterile conditions, since frostbitten tissues seem extremely susceptible to infection. Precautions similar to those employed in the treatment of burns were used, and wet penicillin dressings (1000 units per cubic centimeter) were applied to the blistered and denuded areas. Both patients escaped any loss of tissue except for the loss of the nails (Fig. 7). Although it cannot be stated with certainty that without treatment gangrene would have ensued, there is good reason to assume from previous experience that this would have occurred.

SUMMARY

Gangrene subsequent to exposure to subzero temperatures in a dry surrounding (frostbite) was frequent in wartime and is by no means rare in civilian life.

The exposure to cold leads to a marked increase in capillary permeability that produces a rapid loss of plasma with stranding of the red cells in the capillaries. The red cells tend to stick together and to form occlusive masses, which finally undergo hyalinization.

If heparinization is begun within forty-eight hours of exposure and continued for seven to nine days the occlusive red-cell masses do not form, and subsequent gangrene is thus prevented as shown in animal experiments.

The plasma that leaks into the interstitial space and into blisters forms a dense fibrin deposit.

Heparinization keeps this interstitial fluid liquid and resorbable. Cooling for twenty-four hours after the exposure increases the severity of the lesion.

Warming to 44°C for twenty-four hours after exposure also increases the severity of the lesion. Room temperature seems to be best.

Heparinization of 15 human volunteers exposed to experimental frostbite revealed that gangrene can be prevented by this method. Damage to motor and sensory nerves, however, is not completely avoided.

Sensitivity to cold differs widely between different persons but is rather constant in the same subject. Exclusion of sensitive persons by spot freezing may thus be possible.

Two actual cases of severe exposure to cold that should have led to gangrene were treated by heparinization for five and seven days respectively. Both patients escaped any loss of tissue.

ACUTE SUBPECTORAL ABSCESS A SURGICAL EMERGENCY*

KNOWLES B LAWRENCE, M D,† AND THOMAS J ANGLEM, M D ‡

BOSTON

CASE reports of acute subpectoral abscess and suppurative lymphadenitis — or “subpectoral phlegmon,” as it is sometimes called — have appeared occasionally in both the American¹⁻³ and the foreign^{4, 5} medical literature. The authors usually state that the condition is of relative infrequency, a contention seemingly borne out by a lack of any collected series. A review of the surgical records of the Massachusetts Memorial Hospitals for the past fifteen years reveals a group of 5 cases of acute subpectoral abscess or suppurative lymphadenitis, and 1 case is added from private practice.

Because the nature and behavior of this form of localized suppuration is unfamiliar to many physicians, it is apt to be treated expectantly and conservatively for relatively long periods. Surgery is usually resorted to after the process has spread widely, with extensive tissue destruction, and after a large abscess has broken into the axilla. Unfortunately, during this period the patient has had to endure a painful and toxic course of several days', or even weeks', duration. He may also have run the risk of extension of the suppuration into deeper and more vulnerable regions, such as the subscapular space, the pleural cavities, the mediastinum and the blood stream. Even when these serious complications do not develop he may experience prolonged disability from atrophy of disuse, as well as constricting scar tissue about the shoulder girdle. Surgical drainage is essential, since the sulfonamides and antibiotics cannot be relied on to control this type of infection. The very mechanism by which these agents ameliorate bacterial infection may delay liquefaction of the involved nodes and reduce the local inflammatory signs. As a result it may become more difficult to identify the site of the infection clinically, and the course prior to operative intervention and relief may be prolonged.

The essential pathology in this condition has been described in conjunction with several of the case reports referred to above. Bacteria of high virulence draining through lymphatic vessels from the primary focus, usually a relatively minor infection somewhere in the upper extremity, are filtered out by the infraclavicular lymph nodes. These nodes lie along the courses of the subclavian vessels lateral to the anterior scalenus muscle and the

axillary vessels as far laterally as the axillary fascia and in the adjacent subpectoral adipose tissue. The infected nodes rapidly become swollen and edematous along with the surrounding fat and may proceed to necrosis and frank suppuration within a few days. Kanavel,⁶ who presented an excellent description of the condition, called it a “subpectoral phlegmon.” He considered it to be generally secondary to infection of the middle finger. Occasionally, the primary focus is on the chest wall or shoulder area or not even found. The infecting organism (as in 4 of the 6 cases presented below) is usually a streptococcus. Subpectoral infections due to other organisms, such as a staphylococcus (Case 6), are likely to result in a less fulminating pathologic process and a slower development of frank abscess. The infected mass of lymph nodes and the pus produced in association with it are enclosed in a fascial envelope whose lateral wall is formed by the tough axillary fascia. The relatively high pressure developed within this sac by the expanding inflammatory process provides a reasonable explanation for the great pain suffered by the patients. Edema and congestion of the overlying muscles and other soft tissues undoubtedly contribute to the general swelling of the region and to the symptoms. As the abscess enlarges, the axillary fascia may prove a more effective barrier to the suppuration than the less dense fascial planes beneath the scapula, along the vascular channels into the upper arm or toward the mediastinum. Pus may therefore dissect for considerable distances along these pathways before breaking out into the axilla.

The clinical syndrome in acute subpectoral abscess follows a fairly standard pattern. The patient develops pain in the shoulder and subpectoral area that is usually mild in the beginning but later is often exceedingly severe, there is also some malaise and fever. The shoulder becomes lame, and motion is limited and painful. When the infection is streptococcal the patient rapidly becomes extremely toxic, with a high temperature, chills, excruciating pain in the shoulder area and, in some cases, stupor or delirium. Infections due to other organisms, however, are less likely to manifest these more acutely toxic symptoms. Nearly from the beginning, there is a diffuse, although often only slight, swelling in the subpectoral region, the shoulder, the axilla and, to a lesser extent, the supraclavicular fossa; later, these areas may actually bulge. Tenderness may be marked. There is usually some local heat, redness and perhaps cutaneous edema. There

may be a suggestion of deep induration, particularly beneath the pectoral muscles, but fluctuation usually cannot be elicited. This absence of fluctuation until a late stage of the disease, when a large abscess has broken out into the axilla, has two explanations. Initially, the pathology described above consists of a phlegmonous inflammation of the lymph nodes and surrounding fat, if the patient is seen at that time, of course, no fluctuation can be expected. Secondly, all the tissues involved are enclosed in the tough, resistant envelope of axillary and subpectoral fascia, deep beneath the pectoral muscles. Despite the presence of liquid pus here, fluctuation is difficult to demonstrate, therefore, until the suppuration has broken through the fascia into the subcutaneous fat of the axilla. This may require a week or more. A few small hyperplastic lymph nodes can be felt in the axilla or supraclavicular region but do not impress the examiner as being sufficient to explain the degree of fever and toxicity. The local findings in general suggest an acute inflammatory process in the region of the shoulder, and to those unfamiliar with the syndrome, the actual location of the infection may be puzzling and obscure. The shoulder joint and the neighboring bursas may be under suspicion, particularly since motion in the shoulder joint is limited and painful and the arm is held in some abduction.*

Early incision and drainage of the subpectoral and intraclavicular spaces provide the treatment for this type of infection and are indicated whether a frank abscess or only edematous masses of lymph nodes, with or without beginning suppuration, are encountered. Pain and toxic symptoms are relieved promptly in either case, and there is usually a dramatic fall in the temperature. Surgical drainage also permits bacteriologic studies and identification of organisms that may be susceptible to sulfonamides and antibiotics.

Most of the patients in this series were treated before modern antibacterial agents came into general use. In only 1 case was an agent theoretically specific for the causative bacteria administered in adequate dosage. Since the symptoms and signs failed to improve after more than forty-eight hours of intensive treatment with penicillin preoperatively but responded dramatically to simple incision and drainage of the subpectoral space, it is almost certain that the process would not have resolved under the medical therapy alone. Little actual pus was encountered in this particular case, the chief finding being a mass of swollen and edematous lymph nodes and fat, culture of which revealed a hemolytic streptococcus. Sulfonamides and antibiotics are probably helpful in limiting the spread of the

infection and should therefore be employed in all cases as adjuncts to the surgical treatment.

The technic of surgical drainage is simple. Direct access to a subpectoral abscess may be obtained by incision of the axillary fascia along its junction with the lateral margin of the pectoralis major muscle followed by breaking through of the abscess wall by blunt dissection. If only a mass of infected lymph nodes is encountered, the forefinger may be used to dissect bluntly well up into the space along the axillary vessels as high as the anterior scalenus muscle. A slightly curved skin incision made at right angles to the anterior axillary fold rather than parallel to it should reduce the post-operative scar disability, an important consideration. When necessary, counterincisions are made to gain good dependent drainage, and several Penrose drains are inserted.

CASE REPORTS

CASE 1. C. M., a 54-year-old man was admitted to the Borbank Hospital, Fitchburg, Massachusetts, on July 14, 1939. Four days previously mild chills and fever, with pain and stiffness at the base of the neck on the left, had developed. Three symptoms were interpreted initially as being due to influenza. On the following day the pain became worse, the patient had a high temperature, and a swelling appeared in the left Pectoral region.

When the patient was seen by one of us (T. J. A.) in consultation on the day after admission the temperature was 102°F and he appeared extremely toxic and had some difficulty in breathing. The left pectoral region was involved in a massive, tense swelling extending from the clavicle down over the midportion of the chest and also into the axilla. The overlying skin was cyanotic and showed dilated veins but was not erythematous. The whole area was surprisingly nontender. Aspiration of the region of maximum swelling yielded pus, confirming the diagnosis of subpectoral abscess.

Iodoaloe and drainage were then performed immediately under oxygen and ether anesthesia, the primary incision being placed over the site from which pus had been obtained and extending parallel to the direction of the pectoralis muscle fibers. These fibers were split, giving access to a large abscess cavity extending above almost to the clavicle, medial to the sternum and bulging laterally into the axilla. A large amount of thick yellow pus gushed out. Drains were inserted through counterincisions made in the anterior axilla and on the chest wall into the most dependent parts of the cavity. Bacteriologic studies of the pus showed streptococci.

The patient's general condition improved dramatically, and the temperature dropped gradually, being entirely normal on the 12th postoperative day. There was a short exacerbation of the fever 3 days later, when a hemorrhage followed the removal of a drain and the wound had to be packed. Two or three 1-gm. doses of sulfanilamide but no other chemotherapy were given at that time.

Postoperatively, the patient stated that 7 or 8 days before admission he had accidentally burned the tip of a finger of the left hand. The resulting blister was cut away, and the finger dressed at the shop dispensary. Subsequently the finger became somewhat tender and painful prior to the development of the acute symptoms described above.

This typical case of acute subpectoral abscess was recognized as a surgical condition before serious extension of the process had occurred. It responded well to adequate incision and drainage without the benefit of chemotherapy.

CASE 2. M. D., a 9-year-old schoolgirl, was admitted to the hospital on August 6, 1935. Three weeks previously she

*Cases of similar infections involving the retroperitoneal iliac lymph nodes secondary to a primary focus in a lower extremity have been observed. The responsible organisms in these cases are usually streptococci and dramatic improvement follows surgical drainage of the retroperitoneal spaces.

had sustained a laceration in the region of the right elbow in a fall. After treatment at home the wound appeared to be healing, but 1 week later, after the child had picked off the scab, the arm became swollen, and she complained of pain in the axilla and developed fever and malaise. She was

temperature continued in its septic course, rising at times to 103°F. The white-cell count at that time was 20,050, with 76 per cent neutrophils. When definite fluctuation was demonstrated in the axilla 2 days later, a subpectoral abscess containing over 75 cc of thin, yellowish pus was drained

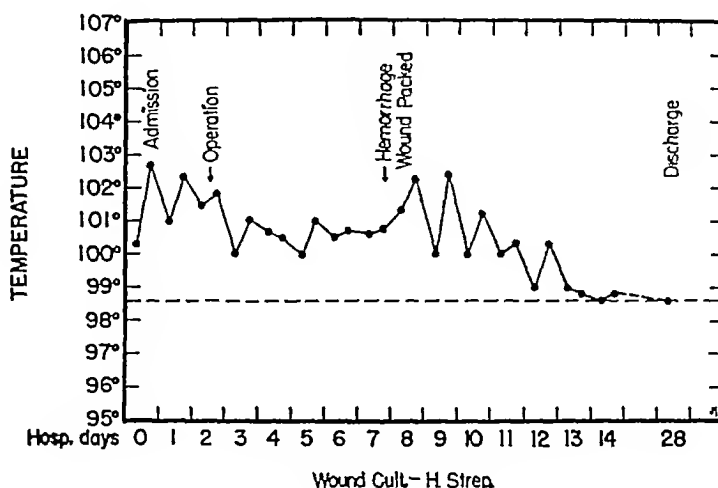

FIGURE 1 Case 1

treated for 1 week or more at home with hot poultices to the axilla, without improvement.

On admission the child appeared sallow and moderately dehydrated. The right arm was held in a position of partial abduction, and shoulder motions were limited in all directions because of the muscle spasm and pain. The right axillary region was tender. Enlarged axillary lymph nodes could be felt, but there was no fluctuation, redness or real

surgically, and a pack inserted. Culture of this pus showed a pure strain of hemolytic streptococcus. The temperature fell to normal within a few hours of the drainage, and the patient made a rapid recovery.

Early recognition of the true lesion in this case would have saved the patient over two weeks of pain and disability.

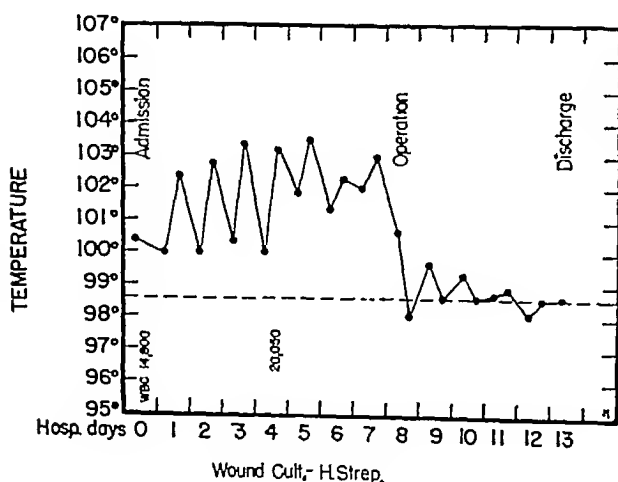

FIGURE 2 Case 2

bulging. A recently healed skin scar was noted over the right olecranon process. The remainder of the physical examination was negative.

The temperature was 100.6°F, the pulse 90, and the respirations 20.

Examination of the blood disclosed a white-cell count of 14,800, with 67 per cent neutrophils. Other laboratory studies were not remarkable. X-ray examination showed a normal chest and no lesion in the bones of the right shoulder girdle.

After 4 days of expectant treatment, swelling of the right pectoral region was apparent, and the right axilla became tender and extremely tender, but never fluctuant. The

CASE 3 H M P, a 28-year-old medical student, was admitted to the hospital on January 23, 1935. Two weeks previously the patient had accidentally pricked the middle finger of the left hand while doing an autopsy. This seemed to heal within a few days, and he was apparently well until 2 days before admission when a pain suddenly developed in the left arm near the shoulder during lifting and became quite severe. During the evening he began to have chills and fever and general malaise. The pain progressed, involving all the left shoulder and the side of the neck. Attempted motion of the shoulder and the left arm was extremely painful.

Physical examination revealed an extremely uncomfortable and moderately toxic patient. The left axillary region seemed slightly swollen and quite tender, and a few small lymph nodes could be felt. The left shoulder anteriorly and the clavicular and pectoral regions were tender to touch. There was only slight swelling in the upper arm and no lymphangitis. A 1-cm healed scar was seen on the dorsum of the left middle finger, with slight redness at its margins. In the absence of actual fluctuation in the axillary region, the attending physicians did not consider surgery to be indicated. The patient continued to experience a great deal of pain in the involved areas and to have fever and chills.

The temperature was 102°F, the pulse 100, and the respirations 25.

A blood culture showed no growth. X-ray films of the shoulder joint and the bones of the shoulder girdle were negative for signs of infection.

On the supposition that this was an acute rheumatic arthritis a course of salicylates was given. The swelling over the anterior aspect of the shoulder and pectoral region increased, and the skin became generally tender to touch, but still fluctuation was absent. The fever continued in its septic course with gradual subsidence to almost normal 10 days after admission. The white-cell count rose, however, to 26,350, with 79 per cent neutrophils on January 28. The pain and the local signs continued, and on February 3, when fluctuation finally became apparent in the anterior axilla, the area was incised with the drainage of 30 cc. of

more of thick, white pus, a culture of which showed hemolytic streptococcus and *Staphylococcus albus*. The fever flared up again, the pain continued, particularly in the upper arm and the white-cell count rose to 34,000. On February 14 surgical drainage of an abscess on the posterior aspect of the left forearm released a great deal of pus. This abscess was found in connect with the original subpectoral abscess cavity. Culture of the forearm cavity showed hemolytic streptococci. The temperature finally reached normal on February 22 as the infected wounds gradually cleared up. Shoulder function returned completely in time, but the patient noticed a numbness of ulnar nerve distribution in the left hand for over 1 year.

Delay in surgical drainage of the subpectoral abscess in this case resulted in local spread of the

phitis. The swelling of the right pectoral region also increased. Some swelling appeared in the axilla and spread in the right shoulder and supraclavicular regions. The patient was then given 25,000 units of penicillin every 3 hours intramuscularly. The temperature, however, continued between 103° and 104°F, and there was no improvement otherwise. The question of pneumonia was raised, but x-ray examination of the chest was negative.

When seen in surgical consultation by one of us (K. B. L.) 2 days after admission the patient was thought to have an acute suppurative lymphadenitis or possibly actual abscess formation in the subpectoral region and was therefore transferred to the main hospital on the afternoon of February 1, for incision and drainage. As a further trial of conservative therapy, the penicillin was continued overnight in doses of 50,000 units intramuscularly every 3 hours. On the following morning, although the temperature had dropped slightly

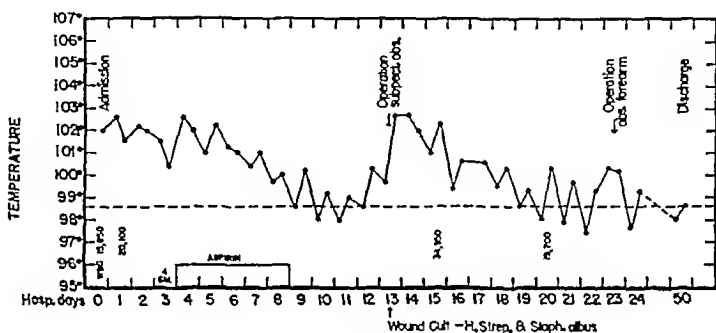

FIGURE 3 Case 3

suppurative process, eventually requiring multiple incisions and a prolonged recovery period. Surgery was deferred until actual fluctuation appeared.

CASE 4 G. C., a 17-year-old boy, was admitted to the hospital on January 30, 1946. Three days previously the patient had accidentally scraped some skin from the knuckle of the right middle finger. On the following day he was able to squeeze a little pus from the wound, and that night developed malaise, insomnia, and a mild chill with fever. He gradually became sicker and on the day before admission the temperature rose to 104.5°F. He vomited and was anorectic. On the morning of admission he was so groggy and toxic and the neck muscles were so stiff and sore that he was thought by his physician to have meningitis and was admitted to the Contagious Department of the Massachusetts Memorial Hospital.

Physical examination showed considerable pain in the right shoulder region, and the patient appeared quite drowsy. There was moderate swelling over the pectoral region, with tenderness on deep palpation. The right arm was held in slight abduction and motion in general, particularly further abduction, was painful. There was some stiffness of the neck muscles, particularly on the right side. There was a recently healed abrasion of the skin on the dorsum of the right middle finger. The remainder of the examination was essentially negative. A lumbar puncture revealed normal fluid.

The temperature was 101.6°F, and the pulse 124. Examination of the blood disclosed a white-cell count of 13,050 with 90 per cent neutrophils. The urine gave a +++ test for ketone bodies but was otherwise normal. The temperature rose gradually to 105°F within 36 hours and the white-cell count to 15,700 with 91 per cent neutro-

phils. The swelling of the right pectoral region also increased. Some swelling appeared in the axilla and spread in the right shoulder and supraclavicular regions. The patient was then given 25,000 units of penicillin every 3 hours intramuscularly. The temperature, however, continued between 103° and 104°F, and there was no improvement otherwise. The question of pneumonia was raised, but x-ray examination of the chest was negative.

In view of the lack of improvement after 60 hours of intramuscular penicillin and fear that the infection was about to penetrate into the mediastinum, incision and drainage of the right subpectoral space were done under endotracheal nitrous oxide and ether anesthesia. A mass of edematous lymph nodes and fat was found filling this space up along the axillary vascular sheath, and several cubic centimeters of thin pus was liberated. Cigarette drains were inserted. Cultures of the pus revealed a mixed growth of hemolytic streptococcus, a streptococcus with alpha hemolysis and a weakly pigmented hemolytic *Staph. aureus*.

Postoperatively the penicillin was continued in the same dosage every 3 hours and sulfadiazine was given in full dosage by mouth, so that a blood level of 8 to 10 mg. per 100 cc. was maintained. The temperature fell dramatically to 100°F within 2 hours of operation and then gradually subsided to normal on the 2nd postoperative day. The clinical symptoms improved nearly as rapidly and the patient was discharged feeling fine, with a nearly normally functioning shoulder and only a slightly draining wound on the 7th postoperative day. The white-cell count at that time was 9,000. Within 2 days, however, the shoulder pain recurred and the patient was readmitted 4 days after discharge with a temperature of 102°F, some toxicity and considerable swelling in the right supraclavicular fossa. The white-cell count at that time was 15,400, with 81 per cent neutrophils. This was considered to represent a flare-up of the infection in the supraclavicular lymph-node group, and not in the subpectoral space. The incision into the sub-

pectoral space was dry and nearly healed, and probing released only a tiny amount of clear serum. The temperature dropped to normal in less than 48 hours on combined treatment with 20,000 units of penicillin every 3 hours and 1 gm. of sulfadiazine every 4 hours. As a safeguard, these drugs were continued for another week, the patient then being discharged cured.

This case represented fulminating suppurative axillary lymphadenitis relieved promptly by early recognition and surgical drainage. Despite intensive administration of penicillin, surgical drainage was necessary to control the principal focus of infection.

CASE 5 R S, a 22-year-old man, was admitted to the hospital on March 17, 1941. Two days previously he had

100°F, where it remained for 5 days. This was thought to be due to a thrombophlebitis of the right axillary and brachial veins that had become apparent at that time. Swelling and soreness of the arm and shoulder subsided with elevation of the arm and moist heat treatment. The patient was discharged on the 16th postoperative day, with only minimal residual disability of the shoulder and arm.

In this case an acute subpectoral lymphadenitis, apparently due to an organism of low virulence, was encountered. No primary focus was found.

CASE 6 A M, a 19-year-old boy, was admitted to the hospital on July 31, 1933. The patient had first noted pain in the right axilla 11 days previously, followed by swelling throughout the upper arm, the shoulder region and the axilla. The pain then became excruciating, particularly on motion.

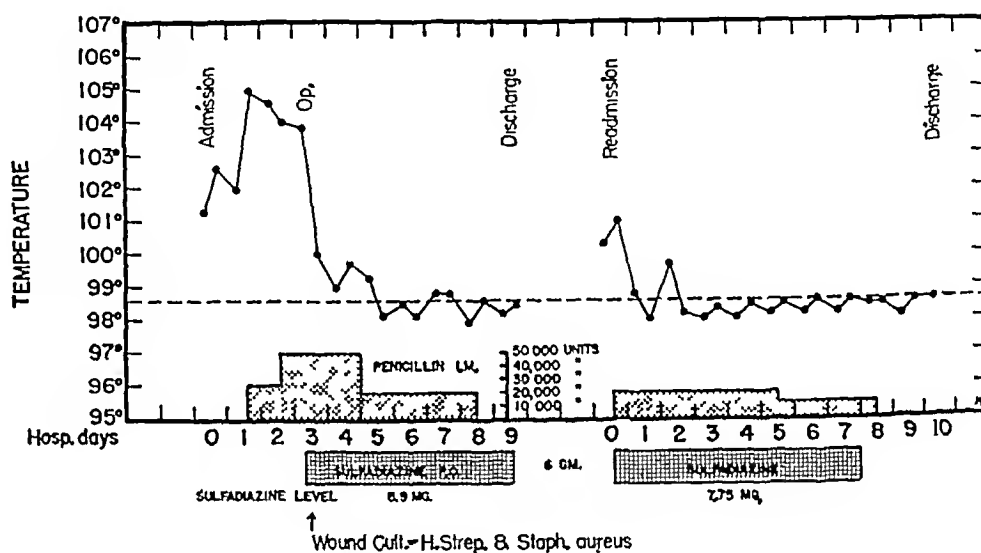

FIGURE 4 Case 4

first noticed pain and swelling of the right shoulder region and upper arm but had felt well otherwise. On the day before admission the swelling extended to the pectoral region, and motion of the shoulder became painful. That evening he had fever without chills. There was no history of trauma or of antecedent infection of any sort.

On physical examination the patient appeared slightly toxic and rather uncomfortable. There was a pronounced swelling, without erythema or edema of the skin, over the entire right pectoral area and to a lesser extent in the axilla and over the region of the anterior shoulder and lower neck. The arm was held at about 20° of abduction, and such movement was painful. Two slightly enlarged tender lymph nodes were felt in the lateral axilla (brachial nodes).

The temperature was 102°F and the pulse 96.

Examination of the blood disclosed a white-cell count of 13,000, with 79 per cent neutrophils. The blood chemical findings and other laboratory studies were normal. X-ray examination of the shoulder girdle showed no evidence of diseased bones or joints. A diagnosis of acute subpectoral abscess or suppurative lymphadenitis was made within a few hours of admission.

Incision was promptly performed by one of us (K. B. L.), revealing an acute edematous mass of lymph nodes in the subpectoral space. This space was thoroughly opened up by incision both through the axilla and down through the subpectoral muscles over the point of maximum swelling. Bacteriologic examination of material from the wound showed a pure culture of *Bacillus subtilis*. The pain was promptly relieved by this procedure. The temperature fell gradually to normal in 48 hours, without a definite purulent discharge at any time. The temperature then rose again to

of the shoulder. The patient became anorexic, somewhat toxic and feverish. Three weeks before admission and 10 days before onset of the symptoms, he had noted a small furuncle just to the right of the sternum, which he had squeezed several times, but later this had seemed to heal.

Physical examination revealed a small, nearly healed furuncle near the sternum. A large, tender, moderately reddened swelling was noted in the region of the right pectoralis major muscles.

The temperature was 100.6°F.
